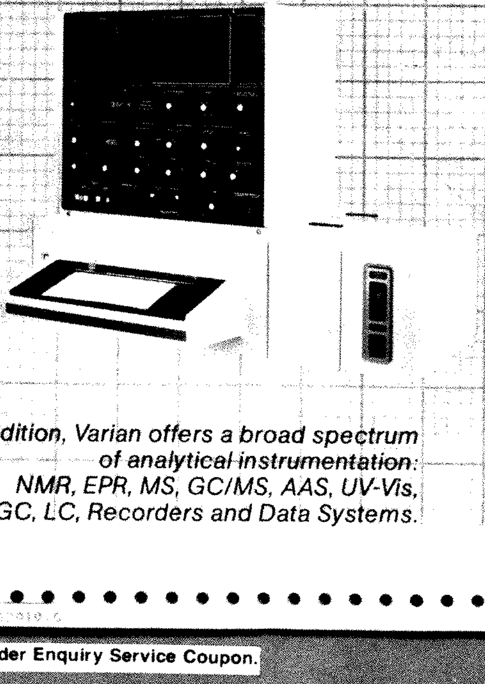
UBULIN ON NERVES

Cary 219

Varian's new UV-Vis spectrophotome... offers the outstanding performance and versatility that scientists take for granted in Cary instruments...

RP394

...at almost
half the usual price
for such performance



In addition, Varian offers a broad spectrum of analytical instrumentation: NMR, EPR, MS, GC/MS, AAS, UV-Vis, GC, LC, Recorders and Data Systems.

varian

Some principal standard features:

Wide photometric range for high and low absorbing samples (−0.6000 to 4.0000 abs).

High sensitivity for low concentrations and weakly absorbing samples (0−0.01 abs full scale).

High accuracy (at 3.0 abs maximum deviation 0.03 abs).

Excellent long-term stability for slow reaction studies (0.0004 abs/hr), with built-in repetitive scanning.

Operational simplicity with automatic source change, automatic baseline compensation and beam reversal.

Plus a wide range of accessories.

For **full** details on the new Cary 219 please circle Reader Service card or write:

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:
(i) only one reference number need be used if the reference is to several papers by identical authors,
(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258,** 1 (1975) and **264,** v, 11 Nov. (1976).

Myogenic defects in human muscular dystrophy — *E. J. Thompson, R. Yasin, G. V. Beers, K. Nurse and S. Al-Ani* 241

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^{a} if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:
(i) only one reference number need be used if the reference is to several papers by identical authors,
(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-55). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

A human leukaemic cell expressing hybrid membrane phenotypes — *G. F. Burns, A. A. Nash, C. P. Worman, C. R. Barker, F. G. J. Hayhoe and J. C. Cawley* 243
Epidermal Langerhans cells bear Fc and C3 receptors — *G. Stingl, E. C. Wolff-Schreiner, W. J. Pichler, F. Gschnait, W. Knapp and K. Wolff* 245
Ia antigen expression on human epidermal Langerhans cells — *G. Rowden, M. G. Lewis and A. K. Sullivan* 247
Epidermal Langerhans cells express Ia antigens — *L. Klareskog, U. M. Tjernlund, U. Forsum and P. A. Peterson* 248
Cytotoxicity against tumour-associated antigens not H–2 restricted — *H. T. Holden and R. B. Herberman* 250
Relationship between β-adrenergic receptors and adenylate cyclase in HeLa cells — *R. C. Henneberry, C. C. Smith and J. F. Tallman* 252
Thyroid hormone controls glucocorticoid action in cultured GH_1 cells — *H. H. Samuels, Z. D. Horwitz, F. Stanley, J. Casanova and L. E. Shapiro* 254
Muscarinic antagonists block cone to horizontal cell transmission in turtle retina — *H. M. Gerschenfeld and M. Piccolino* 257
Lateral interactions in the outer plexiform layer of turtle retinas after atropine block of horizontal cells — *M. Piccolino and H. M. Gerschenfeld* 259
Membrane control of cardiac contractility — *G. B. McClellan and S. Winegrad* 261
Postsynaptic effects of a multiaction giant interneurone on identified snail neurones — *W. Winlow and P. R. Benjamin* 263
Spontaneous release of transmitter from 'repressed' nerve terminals in axolotl muscle — *A. J. Harris, L. Ziskind and D. Wigston* 265
Are transmitter release statistics meaningful? — *S. B. Barton and I. S. Cohen* 267
Replication of EBV in epithelial cells during infectious mononucleosis — *S. M. Lemon, L. M. Hutt, J. E. Shaw, J.-L. H. Li and J. S. Pagano* 268
5′-Terminal nucleotide sequences of polio virus polyribosomal RNA and virion RNA are identical — *R. F. Pettersson, J. B. Flanegan, J. K. Rose and D. Baltimore* 270

BOOK REVIEWS

Darwin and His Flowers: The Key to Natural Selection (Mea Allan) — *R. H. Richens* 273
The Correspondence of Isaac Newton (Rupert A. Hall and Laura Tilling, editors) — *J. W. Herivel* 273
Light and Life (Lars Olaf Björn) — *P. D. Moore* 274
Digital Image Restoration (H. C. Andrews and B. R. Hunt); Digital Picture Analysis (A. Rosenfeld, editor); Image Science Mathematics (C. O. Wilde and E. Barrett, editors) — *P. W. Hawkes* 275
Comparative Immunology (J. L. Marchalonis, editor) — *J. D. Horton* 275
Liquids and Solutions: Structures and Dynamics (P. Kruus) — *H. N. V. Temperley* 276
Intelligence: Nature, Determinants and Consequences (E. B. Brody) — *A. D. B. Clarke* 276

Obituaries

P. Edman — *H D Niall* 279
C. J. Smithells — *G. L. Bailey* 280
R. N. Singh — *P. K. Singh and G E. Fogg* 280
E. Lilly — *F. Hartley* 280

Sex steroid hormone regulation of IgA and IgG in rat uterine secretions *C. R. Wira and C. P. Sandoe* 534

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:
(i) only one reference number need be used if the reference is to several papers by identical authors,
(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258,** 1 (1975) and **264,** v, 11 Nov. (1976).

Chemical structure of attachment sites for viruses on human erythrocytes — *B. J. Enegren and A. T. H. Burness* 536
Synthesis of low molecular weight inhibitor of protein synthesis with enzyme from interferon-treated cells — *A. G. Hovanessian, R. E. Brown and I. M. Kerr* 537
Nature of inhibitor of cell-free protein synthesis formed in response to interferon and double-stranded RNA — *I. M. Kerr, R. E. Brown and A. G. Hovanessian* 540
Effects of sodium butyrate on synthesis on human chorionic gonadotrophin in trophoblastic and non-trophoblastic tumours — *J. Y. Chou, J. C. Robinson and S-S. Wang* 543
Potent prolactin and growth hormone releasing activity of more analogues of Met-enkephalin — *L. Cusan, A. Dupont, G. S. Kledzik, F. Labrie, D. H. Coy and A. V. Schally* 544
A synthetic enkephalin analogue with prolonged parenteral and oral analgesic activity — *D. Roemer, H. H. Buescher, R. C. Hill, J. Pless, W. Bauer, F. Cardinaux, A. Closse, D. Hauser and R. Huguenin* 547
Opiate analgesics inhibit substance P release from rat trigeminal nucleus — *T. M. Jessell and L. L. Iversen* 549
Alterations in dopamine receptor sensitivity by chronic ethanol treatment — *P. L. Hoffman and B. Tabakoff* 551
Desensitisation does not selectively alter sodium channels — *D. H. Lambert, P. M. Spannbauer and R. L. Parsons* 553
Significance of extensive 'leaky' cell junctions in the avian salt gland — *R. A. Ellis, C. C. Goertemiller, Jr and D. L. Stetson* 555
Composition of sarcoplasmic reticulum *in situ* by electron probe X-ray microanalysis — *A. V. Somlyo, H. Shuman and A. P. Somlyo* 556
Myoblast myosin phosphorylation is a prerequisite for actin activation — *S. P. Scordilis and R. S. Adelstein* 558
A synthetic polypeptide with antifreeze activity — *V. S. Ananthanarayanan and C. L. Hew* 560
Effect of light on artificial lipid membranes modified by photoreceptor membrane fragments — *E. E. Fesenko and A. L. Lyubarskiy* 562
Effect of aminoacylation on the conformation of yeast phenylalanine tRNA — *R. Potts, M. J. Fournier and N. C. Ford* 563

MATTERS ARISING

The Star of Bethlehem — *O. Edwards, S. Campbell C. M. Botley, N. R. Flores T. J. Palmer and E. V. Hulse* 565
Reply — *D. W. Hughes* 566

Guide to authors

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

Getting at the truth about Dr Marshall

DR WALTER MARSHALL'S impending departure from his post as chief scientist at the UK Department of Energy (DEN), announced suddenly at the beginning of last week, raises certain obvious questions. Why? Why now? And what are the consequences? The matter is important. The storm accompanying the move has so far only amounted to a survivable squall rather than an intolerable hurricane for the minister who ordered it, Mr Anthony Wedgwood Benn. But it has rightly attracted more publicity than any similar move since the institution of chief scientist became a familiar part of the Whitehall scene. The reason is simple. It seems as though Marshall didn't fall; he was pushed—and almost certainly to make way for someone else.

The question of timing looks easy to answer, but isn't. True, Marshall had just completed the first round of reports on the exploitation of alternative energy sources; and important nuclear decisions are now coming up. Marshall had held two posts simultaneously—chief scientist at the DEN, for which he wasn't paid, and Deputy Chairman of the UK Atomic Energy Authority (UKAEA), with responsibility for its scientific and technical policy. So if he had to go from the former, this was the moment. As the blurb itself 'explained' at the time, Marshall would be resuming work in the UKAEA in view of those upcoming decisions and the UKAEA's 'significant role' in them.

It is not just that there is plenty of work still to be done in the non-nuclear field, in the execution of which Marshall is incidentally now a master, that has left people unsatisfied with this explanation. The various suggestions that Marshall was sacked, which Mr Benn has resented, have been based on the idea that when Marshall acted as Mr Benn's adviser rather than executor, he was 'pro-nuclear'; in other words, he was trying to push Mr Benn into taking early decisions on the choice of reactor issue and the fast breeder, and was generally giving unpalatable advice in an unpalatable manner.

If this argument has any credence at all, it demands refinement. For Marshall, formally speaking, was not Mr Benn's nuclear adviser. That was and is the statutory responsibility of the chairman of the UKAEA, Sir John Hill. Marshall would, of course, have given his view on nuclear issues if and when he was asked. And he had a good working relationship with Hill, his senior at the UKAEA, on responsibilities in this area. But if advice on the nuclear issues with which Mr Benn has become increasingly preoccupied is the reason for Marshall's departure, then *prima facie* it seems the wrong man is going.

Moreover, if the fact that Marshall is 'pro-nuclear' was now causing problems for Mr Benn, it had not caused him to worry in the past. It was Mr Benn who promoted Marshall 18 months ago to the Deputy Chairmanship of the UKAEA, even though Marshall was still to carry on being chief scientist. And it was Marshall who was reluctant to accept the promotion because of the conflict of interest, and who only did so after asking the minister to consider it again and after receiving assurances that he was satisfied.

It is possible that Mr Benn now regards this conflict of interest, much commented on in the past, as intolerable. Certainly Marshall must have felt the need for his departure to be made public immediately for his own personal integrity. But though decisions are due, nothing specific appears to have happened in the past 18 months to make Mr Benn change his mind. Neither is he likely to be grooming Marshall for the UKAEA chairmanship when Sir John Hill's appointment comes up for renewal later this year. Marshall may be only 45 with 20 years of public life left in him, but Hill is 56 and has 10 left himself. Hill's handling of his public relations may have been shocking—indeed appalling on the choice of reactor issue—but there is no sign that he is on his way out.

That being the case, putting Marshall back so precipitately into the UKAEA looks more like a humiliation than anything else. But what could Marshall have done? His record is almost impeccable. He has galvanised the department into action in the field of research and development, producing acclaimed reports on R&D strategy, alternative energy sources and combined heat and power. He has stimulated vitally important work in energy conservation and offshore technology. He has helped Mr Benn to put a young department thoroughly on the map in a way that Mr Benn may not even now appreciate.

Not only that. The consequences of his departure reveal an important paradox surrounding the whole affair. The move is a depressing setback for all those engaged in work on non-nuclear energy, outside as well as inside the department. The loss of morale could prove costly, not least for Mr Benn. At the same time, though, there is little reason to doubt that the affair will *not* prove a setback on the nuclear side, the area in which the real controversies have been raging and on which Marshall would only have given his view in an individual capacity as Mr Benn's personal adviser.

Now this could well have proved a problem, as many people have suggested. Marshall had arrived at particular views. He would have advised that, on the choice of reactor issue, Britain should switch to the pressurised water reactor and export as many as possible; that, on the fast breeder, one big reactor should be built with all deliberate speed; and that, on reprocessing, it should be done for environmental reasons and, by keeping recovered plutonium where it could be controlled, as an anti-proliferation policy.

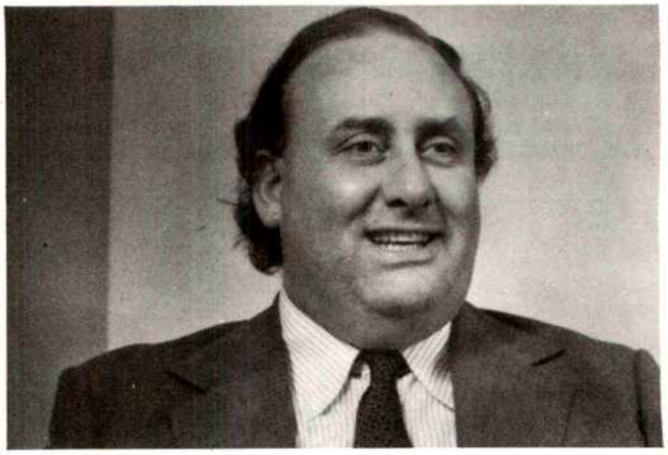
Some or all of this Mr Benn may have found unacceptable. But none of it seems to bear strongly on Marshall's departure, especially given that the UKAEA's position is more stridently 'pro-nuclear'. Only the manner in which such advice would have been given, and the mere fact that it was there impinging on decisions, seems directly relevant. Both of these appear to be strong possibilities.

Marshall and Benn are like chalk and cheese. Marshall will endeavour to appraise a problem and give a considered answer whatever its implications. Asked to do things, he gets them done—and with the department's thinking complete, a 'doer' is what it has needed and still demands. He will be a loss in that respect alone. Mr Benn is different. He must be happy with Marshall's record in executing R&D. But he would have found Marshall irritating to have around with nuclear matters such a big preoccupation. As an ideas man and a political animal to the core, moreover, he needs advisers to brainstorm with who are well-versed politically. And he needs them full-time. Marshall was no intellectual dilletante, and wasn't full-time. Benn is no scientist. And he may not want to get things done.

This other point, that delays are costly, is also important; Mr Benn's advisers have long been urging that decisions be taken. On the other hand, however, the nuclear pause, as Mr Benn calls it, is a bind for bureaucrats, who need goals and the work goals provide—and the nuclear field is a huge chunk of the department's landscape. The industry, too, wants decisions. Now it may well be that in favouring delay for the sake of a public debate Mr Benn has encouraged confrontation, and sought only to ride the back of a good issue for his own personal advancement. But to attribute motives of personal political convenience to actions that have helped to put a complacent industry properly on its toes may be unkind.

Suppose, then, that there may be a good deal in what Mr Benn himself says about now wanting an adviser who can range over the full spectrum of energy matters full-time. If Marshall's nuclear and non-nuclear experience doesn't equip him to do just that, and if it isn't enough simply to speak of Marshall as having suddenly become an unacceptable irritant, there must be a problem above and beyond the fact that to appoint Marshall to a full-time post as adviser would be a rebuff for Sir John Hill. Indeed, not to have made Marshall full-time adviser with a brief ranging over all fields is again a humiliation.

What could this other reason have been? The suddenness of the announcement suggests that the decision was not thought out. But it had apparently been brewing for some time. So perhaps it is better to look at things from the other side. Although it may really be better to announce decisions like this than have them leak out, not announcing a replacement, and saying that an official is to leave 'as soon as possible', is unusual. A presumption has to be made that a replacement will be anounced shortly.



Marshall: did he fall or was he pushed?

That, however, is difficult to do by recruiting from outside civil service ranks, and certainly cannot be done quietly. It is thus more likely that the post will be filled by someone already available. The obvious place to look is among the other chief scientists. Apparently Mr Benn wants another chief scientist as his adviser. And the one who has the necessary experience and who might fit Mr Benn's requirements—more than any other—is Sir Hermann Bondi, chief scientist at the Ministry of Defence. No one else is in sight, and Bondi, having done six years in his present post and being a greater believer in a varied diet, might well find the move attractive.

If that happens, plenty of people would welcome it, not least various people at the Ministry of Defence itself. So one would wonder whether the whole operation was perhaps set up before Marshall's departure was announced. If so, Mr Benn's advocacy of open goverment, sincere as it is, looks thinner as a consequence. More importantly, his experiences with Monty Finniston, Arthur Hawkins and now Walter Marshall suggest that he has a reputation for not being able to get on with his advisers. With such important decisions looming, that is the biggest worry of all. ☐

The concept of usefulness

Among other things, UK research councils are expected to support 'useful' research. In an article based on a lecture given at the Rutherford High Energy Laboratory, Sir Alec Merrison, Vice-Chancellor of Bristol University, comments

SCIENTISTS and society interact in many ways and the interaction is mediated by many agencies. The principal mediating agency in the UK is the government and in turn the government entrusts a great part of its mediating role to the research councils. Society makes demands of scientists and scientists make demands of society and in recent years these demands in both directions have become large.

In the past 15 or 20 years there has been a marked contrast between the mood of society in this country, very much determined by the sense of national failure, and the mood of science everywhere, which has been extremely buoyant. So government has looked to science (and technology) to be 'useful' and this was very much in the mind of the Labour government when it came to power in 1964 and again in the mind of the Tory government of 1970.

It is important to understand that the concept of usefulness is a decidedly limited one when applied to research, indeed it has to be applied with a good deal of taste. It is easy to identify certain research which will probably be useless in the economic sense, and just as easy to identify research which will certainly be useful. But these are limited areas and in between there is a vast body of research whose usefulness it is difficult, if not impossible, to quantify. Look at how much the world has been changed by the discovery 45 years ago of the neutron, and think how much it might be changed in the next 20 years or so by the discoveries of molecular and cell biology. But governments, and *a fortiori* ministers, do not last for 45 (or even 20) years and so, for this and other more compelling reasons, the time-scale is all-important in judging usefulness.

There have been two major revolutions in the past 15 years in the way research councils work: the one set in motion by the Trend Report of 1963 and the one flowing from the White Paper *A Framework for Government Research and Development* in 1972. It was on the Trend Report and the consequent Science and Technology Act of 1965 that our present framework of five research councils has been based. But one of Trend's recommendations, proposing the creation of an Industrial Research and Development Association, was inflated by the then new Labour Government into the now defunct Ministry of Technology. The aim of the 1965 Act was to bring some rationalisation and coherence to the civil research sponsored by public funds, and this it certainly did. But it was a recurrent theme through the 1960s that the research councils were not paying sufficient heed to the nation's needs, insofar as these were expressed by the government's spending departments. In 1970 this found expression in a bid by the Ministry of Agriculture to take over the Agricultural Research Council. This matter was examined by a committee of civil servants, chaired by Mr S. P. Osmond, who recommended that it should happen. Before agreeing, the then Secretary of State for Education and Science asked the Council for Scientific Policy, whose remit it was to advise her on all matters concerning the research councils, to advise her "on the most effective arrangements for organising and supporting pure and applied scientific research and postgraduate training". A small working party under the CSP Chairman, Sir Frederick Dainton, reported to her in May 1971 that its view was that the research councils should be left largely untouched but that the CSP itself should be reformed so that account could be taken of the views on policy held by government departments.

Just after this report was submitted, Lord Rothschild was appointed as first head of the Central Policy Review Staff and the government asked him to review the management of the whole of government research and development including that falling within the purview of the research councils. Lord Rothschild enunciated his now famous 'customer–contractor principle' which was to be applied to all research and development other than basic research. He recommended that in the case of three of the five research councils (Agriculture, Medicine and Natural Environment) there should be a large transfer of their funds to those departments which had an interest in their work. The departments would then use the research councils as their contractors to carry out work which they commissioned.

In the White Paper of July 1972 the government decided that the CSP should indeed be reformed, largely along the lines suggested by the Dainton Committee, and thus it became the Advisory Board for the Research Councils. They accepted too a modified form of Rothschild's customer–contractor principle and his proposal to transfer funds (roughly 50% from the ARC, 30% from NERC and 25% from the MRC). It is perhaps unnecessary to say that rather elaborate machinery has inevitably had to be set up to supervise the allocation of this transferred money.

There are three questions which can be asked in the case of each of these major reforms. Has it made any difference? Has it done society any good? Has it done scientists any good? Now is certainly the right time to ask these questions, since it was the Tory Government's intention when they published their 1972 White Paper that at least five years should elapse before any further substantial change should be contemplated. But in answering them it must be borne in mind that they are essentially questions which are not only difficult to answer, if indeed they can be answered, but also that any answers which can be offered must contain a good deal of subjective judgment.

Both reforms have certainly made a difference and I would imagine that this at least is an answer which would arouse little dissent. So far as the 1965 Act is concerned my own view is that both society and scientists have benefited. A reasonably flexible system has been created which at the same time is sufficiently cohesive that the 'Science Vote' is a good way to control the funds at the disposal of the research councils (not that they are ever enough!).

We are still rather close to the 1972 reforms, but five years later it is difficult to see that they have had any really substantial effect, and such effect that they have had seems to have been for the worse. They have certainly not done the scientists any good, but neither have they done them very much harm (with the possible exception of a good deal of nervousness on the part of scientists working in the more fundamental areas).

What has unquestionably happened is that an unnecessarily elaborate machine has been set up to supervise the spending of the money transferred from the research councils to government departments. This is certainly a loss to both scientists and society and should be reformed. It is wasteful of people's time and is yet another piece of inefficient bureaucracy.

Equally unquestionably, what has not happened is a re-direction of research to any conspicuous degree. One can ascribe this to the incorrigible waywardness of scientists or to the fact that they were not after all quite so insensitive to the needs of society as some people believed. My own view would be that it is largely the latter. At any rate, society is on balance the loser because of the 1972 reforms.

One of the weaknesses of the transferred money system is that once the control of a budget gets into the hands of a spending department then that budget will be at the hazard of all sorts of departmental pressures, few of which will have anything to do with whether the research which might be funded is good or bad. I can hardly believe that last year, when the DHSS decided not to spend nearly a million pounds of its transferred money, it took the decision simply on the grounds that it had come to the conclusion that it was not getting value for money.

So it is a good time to examine carefully the benefits and disadvantages of this way of government departments and research councils working together and, if it really is more trouble than it is worth, to scrap it. It would be good to look too at the whole conspectus of the government's support of 'useful' research and see whether the balance is right. Are we spending the right relative sums on aeronautical research and civil engineering, for example? But if any review is to be undertaken, on a narrow or broad front, I very much hope the reviewers bear in mind the fragile nature of the concept of usefulness in this field. □

OTA's stormy ride

Colin Norman in Washington examines the history and prospects of the Office of Technology Assessment

A SERIES of political upheavals has badly shaken Congress's Office of Technology Assessment (OTA) during the past few weeks, prompting speculation about the future of the fledgling agency and providing ample grist for the rumour mills of Washington's small corps of science policy watchers.

It began on 20 May, when Emilio Q. Daddario, OTA's founder and first Director, announced that he would resign to take an as yet unspecified new job. In his letter of resignation, Daddario said that he felt OTA was firmly established and noted that he had long expressed a desire to leave as soon as the office had reached that point.

Less than a week later Representative Marjorie Holt, a conservative Republican from Maryland, announced her resignation from OTA's Congressional Governing Board. The reason for her departure, she said loudly, was that OTA had been "taken over" by Senator Edward Kennedy, chairman of the board, and she felt that she could no longer make a contribution to OTA's affairs. Her grievances were promptly given a full airing by William Safire, a former speechwriter for Richard Nixon, who wrote a column in the *New York Times* charging that Kennedy had removed Daddario in order to install his own aide, Ellis Mottur, as director.

Then a third blow fell last week. The House of Representatives, acting on a recommendation of its Appropriations Committee, slashed the budget request for OTA next year from $9 million to $7.4 million and decreed that the office's staff level should be reduced to 100, thirty less than now.

This political crossfire is the culmination of a number of tensions which have been building up in OTA ever since it came into being three and a half years ago. The bloodletting that has resulted may ultimately be beneficial for the agency, but much will depend on who succeeds Daddario.

Difficult gestation

OTA's birth followed a long and difficult gestation period which began in the late 1960s. Congress was then beginning to grapple with a series of complex technological issues, such as whether the United States should proceed with construction of an SST and whether an anti-ballistic missile system should be deployed. The debates starkly underlined the fact that Congress lacked the resources to match the technical expertise of the executive branch on such complex matters. At that time Daddario was a Congressman from Connecticut and he held a key position as chairman of the science subcommittee of the former Committee on Science and Astronautics.

After holding a number of hearings with his subcommittee in the late 1960s, Daddario sponsored legislation to create an agency of the Congress to assist in the evaluation of technological matters and to provide an early warning system to pinpoint potential side effects and long term implications of projects and policies involving science and technology. Congress finally passed a bill establishing OTA in October 1972, though by that time Daddario had left Congress to run (unsuccessfully) for the governorship of Connecticut. Kennedy played a leading role in shepherding the bill through the Senate.

The bill specified that OTA would be run by a 13-member board, consisting of 6 Senators, 6 members of the House and the director of OTA. Republicans and Democrats would be equally represented on the board. In addition, the legislation established an independent advisory committee to provide policy advice to the board.

The legislation also specified that the chairmanship of the board should alternate every two years between Senators and House members. Kennedy was elected the first chairman. He was followed by Olin Teague, chairman of the House Committee on Science and Technology, who served during 1975 and 1976, and Kennedy resumed the chairmanship earlier this year. Daddario, meanwhile, was appointed director in 1973 for a six-year term.

OTA represented a major innovation in the Congressional process. It was designed to provide Congress with long-range analysis, act as a counterweight to the technological expertise of the executive branch, and function as an early warning system. It is very much a creature of the Congress, having to respond to the concerns of legislators and provide analyses of issues on a timescale which can effect the passage of particular bills. One OTA staff member last week likened OTA's establishment to an organ transplant: "We grafted it into Congress and waited to see if it would take", he said.

Daddario: just changing jobs?

The graft took slowly, and there have been occasional signs of rejection. First, it took a long time to get the initial studies under way because Congress was slow in appropriating money for OTA. There were also a number of internal problems in securing office space and assembling staff. But OTA began to crank out a huge volume of material. Some 46 studies have now been completed, and 34 more are in the works. Topics have ranged over a broad spectrum, including the bioequivalency of supposedly identical prescription drugs, policies to curb nuclear proliferation, the potential for small scale solar technology (see page 6), and a broad assessment of the impacts of offshore oil and gas production. OTA has also produced a number of critiques of specific administration policies, such as energy plans published by the Energy Research and Development Adminstration (ERDA), President Carter's energy policy, and the research and development strategy of the Environmental Protection Agency.

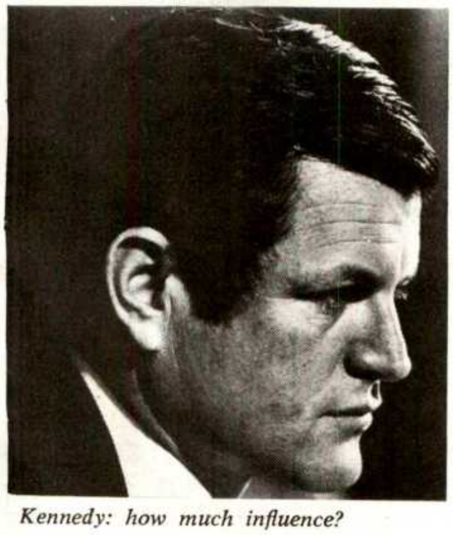
Though arrangements differ from one study to another, the general procedure is to establish an advisory committee of outside experts to help plan and monitor each project. The advisory panels are usually deliberately chosen to reflect diverse points of view, frequently containing members of public interest groups and businessmen. The studies themselves are usually carried out by OTA staff, sometimes with the help of outside contractors, under the guidance of the advisory panels and with overall management provided by a programme director.

Important criticisms

But OTA has run into a number of important criticisms during its short lifetime, and there have been occasional signs that Congress may reject this strange transplant. The grumbles have, however, concerned OTA's style of operation rather than the quality of its reports and analyses.

The first complaints came from OTA's advisory council, which grumbled that it was not being sufficiently consulted on matters of policy. Then, in June last year, the House Commission on Information and Facilities, an obscure Congressional unit headed by Representative Jack Brooks, charged that OTA's internal management was in a mess and that there was general confusion about the agency's mission. That blast was followed by criticism from Harold Brown, now Carter's Secretary of Defense, who resigned last July as chairman of OTA's advisory council and claimed in his letter of resignation that the office had become bogged down in responding to requests for relatively trivial policy studies to the detriment of its primary mission of providing an early warning system. Then last October, a House/Senate conference committee recommended that OTA's budget should be cut and suggested that the fledgling agency had yet to prove its worth to Congress. Finally, from outside OTA have come sporadic complaints that the office has been too cautious in its approach and that it has not really been performing technology assessment.

Asked to comment on some of those criticisms in an interview with *Nature* before he left office, Daddario acknowledged that, "Sure we have had our problems, but every institution in this town has had its problems". He pointed out that most of the criticism was directed at bureaucratic arrangements when OTA was still feeling its way and evolving its style of operation. It has taken three years to develop a sound process to handle the studies, Daddario said, and suggested that it could take at least a decade before the office is functioning smoothly with the full support of the Congress. Daddario noted that none of the criticism has been directed toward the quality or credibility of OTA's studies and it is that, after all, which will ultimately determine the office's influence.



Kennedy: how much influence?

It is indeed possible to point to a number of OTA analyses which had an impact on policy. The critiques of energy policy, for example, suggested that ERDA was paying too little attention to conservation, and the policy was subsequently changed. ERDA Administrator Robert Seamans acknowledged in a press conference early last year that OTA's analyses had played a significant role in shifting funds into conservation programmes in ERDA. The study on offshore oil and gas production has attracted attention and is praised for raising public awareness of many of the central issues involved in the Administration's plans. The drug bioequivalence study, which was the first published by OTA, played a major role in shaping federal policy for drug purchasing under government-financed health care schemes.

Though OTA staffers are quick to note such examples of the office's influence, there has so far been no coherent review of the quality of OTA's reports or the use to which they are put. Two such studies are, however, being planned. The first will be conducted this autumn by the House Committee on Science and Technology, and the second will be carried out by OTA's own advisory council. The latter study was initiated earlier this year by OTA's Congressional board, largely at the urging of Senator Kennedy. And that brings us back to the latest round of political upheavals at OTA.

Kennedy allegations

Allegations that Kennedy planned to take control of OTA were raised when the office was first established and Kennedy was elected chairman of its board. An article in the *Wall Street Journal* in 1973, for example, charged that Kennedy would use OTA as the springboard for his 1974 Presidential election campaign, and in the same vein Safire's recent column in the *New York Times* suggested that Kennedy has little influence on the Carter Administration so he is quietly taking control of OTA to build up his own power base.

Few people deny that Kennedy has a strong influence on OTA affairs. His supporters claim, however, that his influence derives from the fact that he is the most active and interested member of the board. His detractors claim that his influence derives from the fact that some of his own staff members work for OTA and that the chairman of OTA's advisory council, Jerome Weisner, is an old political ally of Kennedy's. It should be noted, however, that Kennedy is not alone in having his own staff working for OTA. Other Senate members of the board have at least one staff liaison with OTA, a fact which has drawn criticism from some other OTA staffers because the political appointees have divided loyalties.

Mrs Holt told *Nature* last week that she resigned from the board because she felt that it "was obvious that we were having no opportunity to make any input at all". On three recent issues Holt was outvoted on the board by Kennedy and his supporters. In each case, she was supported by Teague and the other two House Republicans. The first issue arose when the board refused to reappoint a Texas Instruments executive, Fred Bucy, to a second term on the advisory council. Kennedy opposed the reappointment because Bucy had attended too few meetings in his first term; Holt claimed that Kennedy simply didn't like Bucy's stand on some issues. Second, the board sanctioned a quick assessment of the data which led to the proposed ban on saccharin over Holt's objection that such a study wouldn't add anything to the debate. And third, Holt unsuccessfully resisted a move to have the advisory council conduct a study of OTA's operations.

Underlying the dispute is a significant political gulf between Holt, a conservative Republican, and Kennedy, a prominent liberal Democrat. OTA, in short, has become a battleground for partisan politics.

As for Safire's allegation that Kennedy had engineered Daddario's resignation to pave the way for installing his own candidate in the director's chair, Daddario insisted that his resignation stemmed from nothing more than a desire to change jobs. He said that he had originally planned to stay for only three years but stayed longer to see the solar study and the critique of Carter's energy policy through.

Whether or not these upheavals will leave lasting scars depends largely on who is chosen to succeed Daddario. Kennedy is taking scrupulous care to avoid suspicion that he is trying to influence the selection process. He has asked for nominations from scores of organisations, the advisory council will screen the candidates and the board will make the final selection. So far, the only announced candidate is Daniel V. Desimone, who has been deputy director for the past three and a half years. Ellis Mottur, who now heads a major OTA programme, has been nominated by several groups, but he told *Nature* that he has asked the council not to consider him because his close ties with Kennedy would be sure to encourage Kennedy's opponents.

The next few months are clearly going to be critical for OTA. ☐

Suit to measure

David Davies details a recent US court decision to settle a libel action involving scientists

A RECENT decision in the United States Courts of Appeals has overturned a libel judgment against the *New York Times* and an officer of the National Audubon Society. A New York jury had earlier ruled as libellous accusations in the *Times* that certain named scientists were paid by the pesticide industry to lie by misinterpreting bird-count figures; these figures might have been relevant to the question of DDT's effect on animal life. But the appeal court ruled that the reporting was privileged under the First Amendment.

The dispute arose out of the Audubon Society's report in *American Birds* on its 1971 Christmas Count. The editor, Robert Arbib, wrote a foreword warning that segments of the pesticide industry and certain paid "scientist-spokesmen" were misusing bird counts to prove that bird life is thriving. He continued that apparent increases had in most cases nothing to do with real population dynamics. They were the result of ever increasing numbers of birders, better access, better knowledge and more sophisticated identification. He concluded: "What we are seeing is a result of *not more birds, but more birders.* Any time you hear a 'scientist' say the opposite, you are in the presence of someone who is being paid to lie, or is parrotting something he knows little about".

A *Times* reporter, John Devlin, saw the article and asked Arbib to name some "paid liars". Arbib turned to Roland Clement, the society's Vice-President, for help; Clement provided a list of "consistent misinterpreters" of data, adding however, "We don't have any knowledge of anyone being a paid liar". Whether this qualification was actually passed by Arbib to Devlin was strongly disputed at the original trial.

Devlin next tried to get comments from the five named—J. Gordon Edwards, Thomas Jukes, Robert White-Stevens, Donald Spencer and Norman Borlaug. He reached White-Stevens, Jukes and Spencer, who hotly denied the charges—White-Stevens and Jukes sent copies of their publications. Devlin then wrote his story which appeared in the *Times* in August, 1972. It quoted the Arbib foreword extensively and added that Arbib had said in an interview that the men under attack included the five named. Devlin wrote that those he had reached "ridiculed the accusations as 'emotional', 'hysterical' and unfounded".

There was understandable alarm at the Audubon Society with the *Times* story, and Clement sent round an internal memo that "Arbib was trapped into listing people I have never called liars, though they may be". Clement also dispatched a letter to the *Times* over Arbib's signature saying "it is not simply that more birds are reported because there are more birders, but that we have more birders who are also better birders. Nor do we like to call people liars, but those who have most consistently misused our data [the five scientists were named] . . . have had time to learn from our patient explanations . . . ".

Jukes also wrote to the *Times,* claiming "we have reported these figures in birds per bird watcher". Neither letter was published. Jukes, White-Stevens and Edwards sued for libel and received a total of more than $60,000 in damages against the *Times* and Clement. Arbib was exonerated.

Libel actions by public figures in the United States (and the three plaintiffs were so ruled) can only succeed if it is shown that the libel was motivated by malice—that is, with knowledge that the charges were false, or with reckless disregard of whether they were false or not. The lower court apparently had no doubt that the charges were false and that insufficient care had gone

OTA's bright solar report

GIVEN relatively modest federal support, small solar energy devices could play a significant role in the United States energy picture within a decade, and their potential impact in many developing countries is even greater, according to a massive study published this week by the Congressional Office of Technology Assessment (OTA). Perhaps the most detailed report on solar technologies yet produced, OTA's 1,330-page document is likely to have a major impact on federal policy, coming as it does in the midst of Congressional debate on President Carter's energy proposals.

The report's central message is that the key factor governing the speed with which solar technologies capture the market is the relative cost of conventional energy resources. No major technological breakthroughs are needed for widespread use of solar heaters, and other technologies are also well advanced technically, the report says.

At present, solar heaters can compete economically with electrical heating systems in a limited number of situations, when the capital costs plus the lifetime fuel costs are taken into consideration. But the OTA report suggests that if electricity prices climb by a relatively modest 40% over the next quarter century, solar heaters will be economically attractive in most areas of the country by 1985. Moreover, if 20% of the capital cost of solar heaters could be offset against income tax, they would be competitive much sooner. As for non-electrical heating systems, the OTA report suggests that solar heaters will be cheaper than systems using synthetic gas, but will probably be more expensive than coal-fired systems at least during the next two decades.

The study is also optimistic about the potential for more exotic technologies, such as the direct conversion of solar energy to electricity by photovoltaic cells. Though such devices are now inordinately expensive, the OTA study suggests that the costs could be brought as low as 5–15 cents per kilowatt hour within a decade. That would still be well above present electricity prices, but it may be in line with electricity prices from new generators in the late 1980s. The key, again, is the extent of incentives such as tax breaks for both purchasers and manufacturers of photovoltaic equipment, but research breakthroughs will also be required to bring down the price of photovoltaic cells.

The OTA report breaks new ground in assessing the potential impact of a large solar industry on the labour market, and its findings are likely to enhance the political prospect for solar power. Widespread production and use of small solar units would create employment in such industries as sheet metal-working and light manufacturing which are now experiencing serious unemployment problems, OTA concluded.

Since the rate of introduction of solar technologies depends critically on the relative costs of competing energy sources, solar power is likely to be particularly attractive in countries where fuel costs are high and labour costs are low. Those conditions apply in most developing countries, and thus the OTA study concludes that the potential for solar power in the third world is great. Widespread use of solar technologies would carry the added advantage of reducing international competition for dwindling fossil fuels, and it would also reduce the incentives for developing countries to purchase nuclear plants, the report notes. It is thus in the United States' political and commercial interest to foster an international market for solar technology, the report points out, and the best way to stimulate such a market is for the United States to launch its own domestic solar energy programme.

Colin Norman

into investigating the allegations after the scientists had claimed they were baseless.

The appeal court in no way set aside the findings of the lower court that the accusations were defamatory. Indeed, it used the words "completely foundationless accusation of venality" to describe the charges. What it did rule, however, was that Devlin was insufficiently warned of the falsity of the charges by the scientists' responses, and so could not be accused of malice: "Mere denials, however vehement, are so commonplace . . . that they hardly alert the conscientious reporter to the likelihood of error". Nor, the court ruled, did the "largely irrelevant" mass of materials supplied provide a basis for warning of the falsity of the charges. There was not a "shred of evidence" that Devlin entertained serious doubts concerning the charges.

Further, the court held that even if Devlin had had such doubts, "We do not believe the press may be required under the First Amendment to suppress newsworthy statements merely because it has serious doubts regarding their truth". The public interest in full information required freedom to report charges; accordingly Devlin's article was held to be an "exemplar of fair and dispassionate reporting". Clement was also cleared because it was held that he had not known the *Times* would portray the five as paid liars when he supplied the list to Arbib.

The ways of the law sometimes puzzle scientists and perhaps the most puzzling aspect of this case is how a scientist, told he is to be called a paid liar, can adequately rebut the charge. The court ruled that simply calling the charges "emotional", "hysterical" and unfounded wouldn't even alert a reporter to falsity. Nor would sending him the scientist's stock-in-trade reprints, apparently do. It isn't clear that the appeals court looked at what was sent to the reporter, but they dubbed it "completely irrelevant to the libellous accusations".

It is also noteworthy that the one scientific issue got completely lost in the case—whether the bird statistics establish anything at all. Arbib's foreword claimed that bigger counts per birder arose from better techniques, but then implied that paid liars would simply fail to divide by the number of birders. Devlin did not even mention the question of improved techniques, implying much more strongly that certain scientists don't divide. But the scientists claim that they do and that the figures are still up. The question of better reporting *versus* bigger populations to explain these rises—the nub of the difference between the sides—was hardly advanced at all by this bloody court battle. ☐

ASBESTOS

Amplified evidence

Britain's Advisory Committee on Asbestos held hearings in London last week. Judy Redfearn reports

THAT there is a risk to health from asbestos cannot be denied; but among the general public and in the asbestos industry itself, there are conflicting views on how acceptable that risk is. In March 1976, the UK Health and Safety Commission set up the Advisory Committee on Asbestos to review the risk to different sectors of the public and to come up with recommendations on how asbestos should be used, if indeed it should continue to be used at all. Last week, the committee held three days of public hearings in London when it questioned some of those who had submitted evidence for its consideration.

At the heart of the debate was the acceptability of the asbestos dust levels which were recommended by the committee in an interim statement published in January. Occupational exposure to asbestos dust, that statement said, should be as low as possible, but should not exceed 0.2 fibres per cc when measured over a ten-minute period for crocidolite (blue asbestos, thought to be the most dangerous sort), and 2 fibres per cc averaged over a four-hour period for all other types of asbestos. But the safety of these levels depends on how accurately the incidence of asbestos-related disease can be predicted. As with other diseases caused by long term exposure to certain factors, such as the incidence of lung cancer in smokers, this is very difficult to assess.

The committee's recommended exposure levels were based on the results of a study carried out in 1966 by the British Occupational Hygiene Society (BOHS) on workers in an asbestos factory in Rochdale. The study concluded that an asbestos worker would have a 1% chance of developing an asbestos-related symptom if exposed to 2 fibres per cc for 50 years. A subsequent follow up study at the same factory, however, has come up with some different results.

Dr Julian Peto, of the Department of Health and Social Security's Cancer Epidemiology Unit at Oxford, was responsible for the later study. He told the committee that by the end of 1974 deaths from asbestos-related disease in those exposed for 25 years or more exceeded the total number of expected deaths by 30%. In 1966, the BOHS found nothing unexpected in the death rate. Peto's study also suggested that 5–10% of workers exposed for 50 years to concentrations of 1–2 fibres per cc of asbestos would be likely to die of asbestos-related disease. The discrepancy between the end result in the two studies, Peto suggested, could be due to the cumulative effect of asbestos exposure between 1966 and 1974 and the different way of sampling asbestos workers: Peto's study included all men who had been exposed to asbestos for 10 years or more between 1933 and 1972, whereas the BOHS study only included those still in employment there in 1966.

Furthermore, Peto told of evidence that chrysotile (white asbestos) could be as potent as crocidolite in causing asbestosis and pleural mesothelioma, an inoperable cancer of the membrane surrounding the lung. All in all he felt there was strong evidence that the present 2 fibres per cc level is inadequate but that there should be more research, especially into factors such as the effectiveness of pulmonary clearance below 2 fibres per cc.

But concern does not only centre on workers in asbestos factories. Asbestos is so widely used that most people at some time will have been exposed to it. Pressure is increasing to ban certain applications of asbestos such as asbestos paints and sprays and domestic use in general. The British Society for Social Responsibility in Science (BSSRS), using its evidence that cases of asbestosis and mesolthelioma have resulted from very short exposures to asbestos, is calling for a total ban on its use; it suggests that in the meantime personal protection for asbestos workers should be improved and safe substitutes should be introduced as soon as they are developed. But even a far more stringent standard poses problems. The recommendation from the Trades Union Congress of a 0.2 fibres per cc standard was thought technically impossible to achieve for most manufacturing processes, especially the dry processes which create a lot of dust and which are found in the asbestos textile industry.

The committee's task now is to digest the evidence gathered at the hearings and to call others forward to explain their case. No one yet knows when it will produce its report laying down recommendations for the future use of asbestos. There are provisions, however, for another interim report to be published if the evidence suggests that speedy changes are needed to the present ways of dealing with asbestos. ☐

CZECHOSLOVAKIA

In a sorry state

Vera Rich reports on recent evidence of harassment of dissident Czechoslovak scientists

CZECHOSLOVAK scientists whose "moral and political requirements" fail to meet the official standard are not permitted to publish their scientific work. This was revealed by a 270-page White Paper on Czechoslovakia published last week the International Committee for the Support of Charter 77.

The Order was first made known in a letter from the Czechoslovak Ministry of Education to the Charles University, Prague, in May 1972, and in spite of protests has never been revoked. Since recent government moves against the Charter 77 movements include widespread dismissals of known signatories, the order on publication has taken on renewed importance.

One man who visited London to launch the White Paper, Dr Zdenek Mlynar, was dismissed from the Entomological Department of the National Museum for being a member by the International Committee for the campaign known as Charter 77". Now in exile, he says that with the new waves of dismissals of the known Chartists from the Party and from professional employment, "Prague today is full of highly educated men sweeping the streets and stoking boilers".

These dismissals differ in one respect from those of the post-Dubcek repressions of 1970. Then it was primarily the social sciences which were hit—offending natural scientists were demoted but normally remained in their field of research. Today, however, the campaign against the Chartists makes no distinction between natural or social scientists; all are equally liable to dismissal, under the regulations on political attitudes.

These regulations, quoted in the white paper, actually antedate the Charter. The Directives of the Secretary General of the Academy of Sciences of July 1976 noted that "All creative and economic-technical employees shall have to be qualified in terms of politicals maturity . . ."; and all leading "scientific workers" of the Academy were requested to complete a questionnaire concerning their political activities and Party status, and also that of their close relatives.

Following the appearance of the Charter, there was a wave of summary dismissals of known Chartists, including Dr Mlynar himself, from academic posts without the customary period of notice; it was "not possible" for the Chartists to remain during the normal termination period "without jeopardising the orderly fulfilment of the organisation's tasks." Under the 1972 regulations on publication, scientists thus dismissed not only lose their posts; they are unable to publish work in hand, or undertake such fringe activities as translation.

When the restrictions first became known, Dr Frantisek Janouch, in a letter of protest to the Minister of Education, Josef Havlin, pointed out that they would inhibit the dissemination of "valuable information on new findings" solely because their authors' "moral-political profile does not comply with a certain set of curious criteria which have never been publicly announced". In the case of the Chartists, the criteria are even more curious because the Charter and its subsequent documents make no demands which are not already stipulated either in the Czech constitution or in the international human rights agreements to which Czechoslovakia is a signatory.

Whatever the criteria, however, the dismissal of scientists and the ban on publication are a considerable threat to Czechoslovak science. It is already difficult, said Dr Mlynar, to function adequately as a scientist in Czechoslovakia: personal international contacts are now only 10% of what they were in 1968; foreign currency restrictions have brought about a general drop in the standard of equipment and in the accessibility of foreign journals.

Now there is also a threat to the next generation of scientists. A large collection of documents in the white paper presents unequivocal evidence that parents' political attitudes are a prime factor in deciding university admissions. Again, this trend antedates the Charter; Document 4 of the Chartist movement (23 January 1977) specifically calls for an independent inquiry into this practice. This demand has not been met. □

WEST GERMANY

Saving it

The West German government has plans to encourage energy saving. Werner Gries explains how

CONDITIONED by the oil crisis the Federal Republic of Germany has now moved energy-saving to the foreground of its energy policy. It has put special emphasis on reducing energy losses in electricity generation, saving energy in heating supply, and saving energy used by traffic.

On the domestic front low interest loans have been allocated to finance energy-saving measures. Definitive regulations about heat insulation for housing construction have been laid down in energy saving legislation and new buildings will have to be better insulated in future. Firing installations in residential buildings will also have to be made more efficient. This will increase the cost of building houses by approximately 3%.

Industry is to be granted 7.5% of its expenditure on energy-saving investments and special investment credits are already available. In the public sector energy-saving measures are being considered in building plans and public education in energy saving is being intensified. In research, prototype projects for the efficient use of energy are being supported directly by the Research Ministry; over the past three years about DM500 million have been made available for this purpose.

The government is at present working out a detailed programme. At the heart of further domestic measures are investments to improve heat insulation and installations for heating supply. Heat pumps and solar collectors are also to be promoted through state allowances. The tenancy law is being altered to encourage energy saving. The government also wants to modify electricity tariffs and possibly make it a duty to mark the energy consumption on household appliances.

The focus in industry is on the coupling of electricity and heat production. An investment of DM2,400 million is to be spent on district heating up to 1980. Thought is also being given to taxing cars with diesel engines less than those with petrol engines and new driving systems (methanol cars and electric cars for example) are being encouraged through tax incentives. Most of the government measures, however, will only complement private initiatives and interventions will be limited. □

SWEDEN

● The National Environment Protection Board has proposed to the government that, from 1 January 1979, no aerosol pack containing halocarbons as a propellant should be made in Sweden or imported without permission from the Board's Product Control Division.

The Swedish initiative follows American research into aerosol packs and their effect on the ozone layer—an area in which the Swedes have not done any independent research. The present proposal was stimulated by last May's joint recommendation by America's Food and Drug Administration, Environmental Protection Agency and Consumer Product Safety Commission that would forbid the manufacture of halocarbons or of sprays containing them and the sale of both by April 1979.

The American recommendation exempts aerosols for certain essential uses, mainly medical (sprays for asthmatics, for example), and envisages other uses deemed essential in the future being added to the list of exemptions. The Product Control Division chemist who wrote the Swedish proposal, Ingrid Jedvall, sees much the same sort of situation emerging in Sweden, with certain aerosols being given permission to be sold. As an administrator she prefers her proposal to the American one because if all decisions about particular aerosols are taken within the division, no publication and updating of exemptions will be necessary. It could also be argued that the public should be informed which aerosols are being sold at any time. Critics will no doubt label the proposal as typical of a Swedish trend, which they see as government by bureaucrats whose tenure does not depend on responsibility to the people.

Sweden does not manufacture halocarbons, and uses less than 1% of the world's consumption. In 1975, the country used about 5,200 tons of halocarbons, but this amount has decreased to the extent that the 1977 total is expected to be only about 1,200 tons. The 1975 amount was used in the following proportions: cosmetics 65%, household products 6%, medical and veterinary 3%, colour, waxes and polishers 9%, insecticides 4%, products used in industry 12%, and other uses 1%. In the same year, 29 million packs were sold, an average of about 3.5 for every inhabitant.

The decreased use of halocarbons is partly due to changes in production introduced successively since 1973 by the Aerosol Packing Co., which sells 75% of aerosol cans in Sweden. It has changed from halocarbons to propane and butane and, as a company spokesman pointed out, will not be at all dismayed if halocarbons are regulated. To offset the fire risk present during manufacture under the new régime, the company has computerised the system so that the cans are monitored and the whole system can shut off automatically if concentrations of the gases reach the danger zone.

● Sweden's first wind power station was recently opened on the coast north of Stockholm, at Älvkarleby. Its 18-metre-wide vane, which rotates about an axis perched on top of a tower 25 metres high, generates between 50 and 63 kilowatts. Ungainly though it looks, its computer—which automatically adjusts the angle of the vane to the wind—should provide the state Committee for Energy Research with useful data about the way its design stands up to stress and vibrations under different wind conditions. It is, says one committee member, Sven Hugosson, a sort of laboratory bench unit whose performance will determine whether it will be worth building others of the same type. The first evaluations of the way it is going will be made this summer.

Whatever the results, they will not influence the next phase of the Committee's wind programme, due to begin in August. Three full-size wind power stations, each generating 2 megawatts but differing in design, will be located in various parts of the country with the help of a survey done by the Meteorological Institute describing wind conditions around the coasts. Their performances will determine which designs will be built in future. At the opening of the Älvkarleby station the Energy Minister, Olof Johansson, looked forward to the turn of the century, when he envisaged wind energy providing between 4,000 and 10,000 megawatts.

Sven Hugosson says he does not doubt the technical feasibility of wind power for Sweden, but that very little money has so far been appropriated for experimentation. He does not think it could replace any other source of energy, but is certain it could play a part—especially in conjunction with hydro-power—in providing total energy needs. It does have, however, some surprising hazards: chunks of ice may be flung off the vane in winter and scattered like mini-missiles.

Wendy Barnaby

IN BRIEF

JET: still waiting

Some intensive lobbying is expected throughout Europe over the next couple of weeks in the run-up to the EEC Council of Foreign Ministers in Brussels on 25–26 June, when a decision on the siting of the Joint European Torus (JET) fusion project is now due. The subject came up at the meeting of European heads of government in London last week. Reports of a West German effort to secure a greater UK contribution to the Community budget in return for the project going to Culham instead of Garching were not in the event borne out. The leaders failed to agree and the matter was passed over to the Foreign Ministers for them to decide in a make-or-break meeting.

At a press conference after the meeting, the UK Prime Minister, James Callaghan, said he doubted whether any individual country could carry on on its own if a solution satisfactory to everybody wasn't reached. But with such an excellent team at Culham, he said, "It would be my desire to see whether we could work out bilateral, trilateral, quadrilateral or multilateral agreements with any group of countries that will keep the project in Europe, even if it wasn't a European project in the technical sense".

World climate conference

At its 29th session in Geneva last month the executive committee of the World Meteorological Organisation (WMO) decided to convene in 1979 what it calls a high-level scientific and technical conference, called the World Climate Conference, gathering together meteorologists and experts on the effects of climate on economies.

The timetable of the first global experiment of the Global Atmospheric Research Programme (GARP) was approved. Gathering of atmospheric and oceanographic data for research will be planned this year and observations will be carried out from December 1978 to November 1979, especially during January–February and May–June 1979. The aim of the experiment will be to improve meteorological forecasts and to obtain a better understanding of climate.

Energy balance urged

Governmental machinery for striking the right balance between different energy sources, bearing in mind not only availability but the differing community and environmental costs, is "entirely lacking', says Sir Peter Kent in a letter to *The Times* this week. Sir Peter, chairman of the UK Natural

Environment Research Council (NERC), would like to see some interdepartmental organisation established —perhaps within the Cabinet Office— "to demonstrate that the energy problem is regarded as transcending departmental boundaries". Factual data are, he claims, entirely inadequate at present for the general public, and the conventional public inquiry is too narrow in its scope to allow for truly informed decisions. In his opinion, the research council system could be of value in providing independent and authoritative data for such enquiries.

SRC appointment

The UK Science Research Council last week announced the appointment of Mr A. M. Adye (49) as its first Director of Marine Technology. He became Director on 2 May and is on secondment from British Petroleum Ltd.

The SRC's Marine Technology programme itself is new: it was announced only last year. Its aim is to involve academic institutions in all aspects of marine technology and to encourage postgraduate engineers to take up opportunities in the exploitation of the sea and sea-bed resources. Eventually, the Marine Technology Directorate hopes to promote the development of centres of expertise in marine technology in universities and polytechnics.

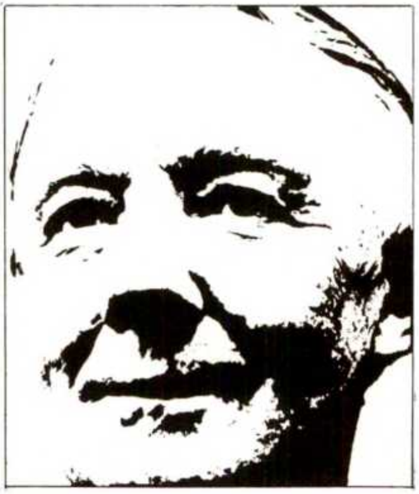
A Management Committee of six members will determine the outline of the programme, and three assessors from the Department of Energy, Department of Industry and Ministry of Defence will also be involved.

Energy body announced

The UK Secretary for Energy, Mr Benn, announced last week the composition of the Energy Commission which is being set up to advise the government on the development of an energy strategy for Britain.

Seven members of the 23-man Commission will be the chairmen of the National Coal Board, the Electricity Council, the British Gas Corporation, the United Kingdom Atomic Energy Authority, the British National Oil Corporation, the South of Scotland Electricity Board and the Petroleum Industry Advisory Committee. Seven others will be drawn from the TUC Fuel and Power Industries Committee, and the remaining seven, whose names will be announced shortly, will represent other industries and consumer interests. The Minister of State for the Scottish Office will also be a member and the chair will be taken by the Secretary of State for Energy.

The biter bit



KENNETH MELLANBY

As an entomologist I spent many years killing insects. During the 1939–45 war I played some part in controlling medical pests in Britain, Africa and South East Asia, and was involved in operations where large amounts of toxic insecticides were widely and effectively distributed. I have also had some experience with agricultural pests, and nuisance problems such as swarms of gnats breeding in sewage plants. I was not the friend of the insect world, and so should not have been surprised when I suffered from its attentions.

As an undergraduate, I took part in an expedition to the Canadian Arctic. We made botanical collections and anthropological measurements of Eskimos, but it was the biting insects which impressed me most and which probably diverted my career from either medicine or botany. The most effective repellant then available was citronella oil, but liberal applications of it, a thick veil and army puttees did not prevent me from receiving thousands of mosquito bites. There are probably drops of blood from my wounds on the dried plants which were eventually sent to the herbarium at Kew in England.

Another revolting creature which has added to my sufferings is the bedbug. As a young research student at the London School of Hygiene and Tropical Medicine, I lived in a seedy flat in Soho which we kept reasonably bug free, but on hot summer nights these insects, moving out of less well maintained property, crawled in at the windows until these were surrounded with sticky bands of the grease used to stop pests climbing up fruit trees. I met bedbugs in every country I visited—in wicker chairs in Ceylon, where they bit the backs of my bare knees, in a rather grand hotel in Calcutta where I caught over 200 in an hour and sent them to the manager with my compliments, and even in Stockholm, Sweden, in a cheap hotel in a picturesque part of the old city, now replaced by hideous modern buildings.

Then about ten years ago I lectured to the British Association for the Advancement of Science on 'Insecticides'. Halfway through my talk I felt a painful jab in my scalp; I had been stung by a wasp. With true British *savoire faire* I remarked, casually, to my audience, "I've been stung by a wasp", and continued my lecture. But somehow the press got to know, and next morning the national newspapers contained the story with the headline: 'Insect world strikes back'.

And now it has struck again. This summer my seventeenth century farmhouse in rural England has developed a massive attack of Death Watch Beetle. I was laid up in bed for a few days, and on a warm afternoon towards the end of May I observed hundreds of these beetles emerge from what the house agents would call the 'wealth of old oak beams'. They crawled actively in all directions, and, when the temperature was above 22 °C, many flew vigorously and dashed themselves against the window panes. It was only the bedroom I occupied that produced swarms of beetles; the rest of the house yielded very few. The attack was obviously aimed at me, personally.

In some ways this is a bit unfair. For the last few years I have mended my ways, and have been mainly involved in wildlife conservation. I have helped to control the use of the more dangerous insecticides, as part of an attempt to safeguard the environment. I have banned pesticides from my garden, and have relied on the inefficient help of beneficial insects. But the Death Watch Beetle has gone too far. Now I have willingly agreed to have my house impregnated with one of the organochlorine insecticides. This is being done with care, and I hope that little will escape to harm the birds and insects in the garden. But this is war to the death, and nature must take its chance. I am even reconsidering my policy for pest control in our garden.

Population genetics and cultural inheritance

from Robert M. May

Many of the central questions of our time, both at the barricades and in the ivory tower, turn upon the relative contribution made by genes and by environment to the behaviour of individuals.

Disentangling these factors in any specific situation is often made forbiddingly difficult by the fact that the contribution of nature depends on nurture, and that of nurture depends on nature. Medawar (*New York Review of Books* **24** (1), 13; 1977) gives an illuminating example. The little brackish water shrimp *Gammarus chevreuxi* begins life with red eyes, but usually ends up with black eyes. This blackness arises from the deposition of melanin in the eye, a process which depends both upon the genetic predisposition to form and deposit melanin, and upon the temperature and other features of the environment. Particular genotypes can be chosen such that the eye colour is determined wholly environmentally (black at relatively high temperature, red at low); conversely, it is possible to choose temperatures such that the eye colour is inherited in perfect Mendelian fashion, like the classic peas. The simple question 'what percentage of colouration of the eye is due to heredity?' is meaningless. Of course, for cases like this shrimp, or for most plant and animal breeding, the relative contributions of nature and nurture can be sorted out by careful programmes of study and experiment. For human societies, the relative roles of heredity and culture (or, to use a word newly minted by Dawkins in *The Selfish Gene*, Oxford, 1976, of genes and 'memes'), are manifestly more difficult to disentangle. Furthermore, as Medawar has lamented (*op. cit.*): "The subject is bedeviled more than any other by the tendency of disputants to spring into political postures which allow them no freedom of movement. Thus it is a canon of high tory philosophy that a man's *breeding*—his genetic makeup—determines absolutely his abilities, his destiny, and his deserts; and it is no less characteristic of Marxism that, men being born equal, a man is what his environment and his upbringing make of him. The former belief lies at the root of racism, fascism, and all other attempts to 'make nature herself an accomplice in the crime of political inequality' (Condorcet) and the latter founders on the fallacy of human genetic equality ('A strange belief,' said J. B. S. Haldane—a long-time member of the CP)."

It would be nice if we could turn to theoretical population genetics for help. The mainstream of this subject, however, is devoted to increasingly elaborate studies of the way gene frequencies behave under the influences of mutation, migration, drift and abstract selective forces; the selection is rarely tied to concrete environmental realities.

Models for cultural inheritance

Of great interest, therefore, is the recent work of Feldman and Cavalli-Sforza (*Theor. Pop. Biol.* **4**, 42, 1973; *Amer. J. hum. Genet.* **25**, 618, 1973; *Annls hum. Biol.* **2**, 215; 1975; see also Karlin & Carmelli *Proc. natn. Acad. Sci. U.S.A.* **71**, 4727, 1974; and Lewontin *Am. J. hum. Genet.* **26**, 400, 1974). Although still in the formative stages, this work treats models for cultural inheritance, and seeks to show how traits may evolve under combined genetic and phenotypic transmission.

The most recent of these studies (Feldman & Cavalli-Sforza *Theor. Pop. Biol.* **9**, 238; 1976) begins with the familiar artifice of a trait that depends on one locus with two alleles, A and a, thus leading to the three genotypes AA, Aa, aa. Now comes the twist: adult individuals are characterised not only by their genotype, but also by whether or not they possess a certain unspecified skill. There are thus six possible phenotypes, the skilled ones $\overline{AA}$, $\overline{Aa}$, $\overline{aa}$ and the unskilled ones AA, Aa, aa. For the initial study, one parent, who may or may not be skilled, is arbitrarily defined as the "teaching parent". In general, the 'educability' of the offspring will depend on its genotype so that the probability that a given individual will grow up to be skilled now depends both on the genotype of the individual (his nature) and on whether the teaching parent is skilled (his nurture). Finally, it is supposed that selection occurs; the six different phenotypes will have relative reproductive success rates that depend on their genotypes and on their acquisition of the skill.

The assumption is now made (more for convenience than from conviction) that mating occurs at random with respect to skill and genotype. Equations may then be constructed relating the frequency of the genes A and a, and the proportions of skilled compared with unskilled individuals for each of the three genotypes, between successive generations. In their most general form, these equations are highly complicated: I shall return to this below.

Feldman and Cavalli-Sforza extract interesting results by making various simplifying assumptions. In the first case they assume that the selection coefficients depend only on whether the individual is skilled or not; the relative reproductive success of any skilled to any unskilled phenotype is $1+s:1$, independent of the genotype. The genotype is of course still important in determining the probability that the phenotype will be skilled (by influencing the 'educability' of the individual), but the selection coefficients do not depend on the genotype as such. On the assumption that unskilled teaching parents never raise skilled offspring, it can be shown that the maintenance of genetic polymorphism (both A and a present at equilibrium) requires not only that heterozygotes (Aa) be more receptive to the skill of the parent

---

Robert M. May is the Class of 1877 Professor of Zoology at Princeton University.

than are the homozygotes (AA and aa), but also that this 'overdominance' in heterozygotes' learning ability must exceed some threshold that depends on the selection parameter s. The authors give as a numerical example the case where a skilled teaching parent raises 70% of its AA or aa offspring to be skilled compared with 80% of the Aa offspring; polymorphism is maintained only if the selective margin in favour of skill exceeds 1/3 (that is, $s>1/3$; $1+s:1>4:3$). This is in contrast with conventional population genetics, where heterozygote superiority ensures stable polymorphism.

In the second case, Feldman and Cavalli-Sforza make a further simplification and assume that all offspring of skilled teaching parents are skilled. There is now completely accurate copying of the teaching parent (skilled or unskilled) by all offspring, irrespective of genotype. Nurture is all-important; nature is irrelevant. Obviously, the final state is for all the population to be skilled (providing the skill is advantageous, $s>0$). Less obviously, there is no unique value for the frequency of the genes A and a; rather, there is a neutral equilibrium, with the gene frequency depending on the initial distribution of the skill effects. Even though there are no genetically based selection differences, substantial changes in gene frequency can occur over time if there are initial differences in the distribution of the skill among the genotypes. As an example, the authors assume that the alleles A and a are initially equally common, and that the initial fractions of the genotypes AA, Aa and aa that are skilled are 90%, 50% and 10% respectively: this system will eventually settle to have the frequency of the alleles A and a around 65% and 35% respectively, corresponding to a 30% change in gene frequency. To the unsophisticated observer, it might appear that the 'superior' gene A has asserted itself; in fact, this relatively large gene frequency change is due to a kind of founder effect in a situation where all genotypes are equivalent.

Up to this point, it has been assumed that the probability of acquiring the skill (with consequent selective advantage s) depends on one 'teaching' parent. The authors next consider the case where both parents affect the outcome. To keep things manageable, the genotype of the offspring is assumed to be irrelevant; the probability that an individual will grow up to be skilled depends only on the phenotype of both parents. In these cases, the gene frequencies of A and a approach some neutral equilibrium, determined by initial values. In contrast, the phenotypic proportions of skilled and unskilled individuals converge to equilibrium values that depend on s and on the probabilities for given parental combinations to produce skilled offspring. Depending on the relations between these parameters, there may be a unique stable state, or two alternate stable states, or even (in rather extreme circumstances) stable cycles in the proportions of skilled phenotypes.

Disadvantageous 'cultural' traits: the 'kuru model'

In the models where acquisition of the skill depends on both parents, it is interesting to consider the case where the 'skill' confers a disadvantage ($s<0$). Such could be the case where an infectious disease or other such disadvantageous trait is transmitted from parent to offspring. Feldman and Cavalli-Sforza show that 'a strongly disadvantageous custom can spread through a group provided there is enough pressure on the members of the group to conform to the custom' (page 257). The authors refer to this as 'the kuru model', after the degenerative brain disease found among the South Fore linguistic group in the Eastern Highlands of New Guinea, and thought to derive from a slow virus (similar to that producing the rare Creutzfeldt–Jakob disease) transmitted by the custom of eating or sniffing the brain of dead relatives. The authors add that 'in these cases it would be of considerable interest to introduce the added feature of finite population size in order to

New shocks in northeastern Alaska

from Peter J. Smith

EARTH scientists have often displayed a tendency to interpret a lack of data prematurely in terms of simplicity, presumably through an over-literal application of Occam's Razor. Only a few years ago, for example, it was not uncommon to find the upper mantle being described without qualification as physically homogeneous; and yet as more and more data have accumulated the illusion of homogeneity has receded. This happens to be one of the classic examples of oversimplification through ignorance, but there are many hundreds of others of various degrees of importance, one of which has now been revealed for what it is by Gedney *et al.* (*Geophys. Res. Lett.* **4**, 175; 1977).

This new case, which concerns the seismicity of northeastern Alaska, is perhaps of minor importance scientifically but warrants attention because of its political overtones. In April 1976 Meyers (*NOAA Technical Memorandum EDS NGSDG-1*) could find mention of only 10 earthquakes having occurred in Alaska north of 68°N throughout the whole of recorded history, thereby apparently confirming the widely held view that northeastern Alaska is relatively aseismic. The fact is, however, that the first seismograph station in Alaska was not constructed until 1935, and from then until 1966 the station closest to the northeastern corner of the state lay several hundred kilometres away near Fairbanks. Moreover, even as recently as 1975 there was no station closer than Fort Yukon on the Arctic Circle. In short, the detection threshold for earthquakes in northeastern Alaska has traditionally been high.

But all that changed during 1975–1976 when Gedney and his colleagues installed nine new seismographs in the Brooks Range. This sounds easier than it was, for access to much of this area is by helicopter only. Maintenance during the winter months is therefore impossible; and the recording equipment has been usable for only about half of the time. Nevertheless, during 1976 no fewer than 69 earthquakes in the magnitude range 1–4 were recorded and located (44 of them north of 68°N) and many others were detected but could not be precisely located because of low shock magnitude or equipment failure. In other words, the result of a drastic reduction in the threshold detection limit (from about magnitude 4 to magnitude 1) has been to erase the mistaken impression that the northeastern corner of Alaska has a very low seismicity.

This may not be the first time that an area has been shown to be more seismic than previously supposed. The point about northeastern Alaska, however, is that it is the site of the northern section of the oil pipeline and of the Alaskan section of the proposed natural gas pipeline through Canada. The northern part of the oil pipeline has in fact been designed to withstand shocks in excess of magnitude 4. But discoveries such as that by Gedney *et al.* are bound to strengthen the environmentalists' insistence that any new pipeline projects should be deferred until the data available are adequate to rule out even nastier surprises.

Peter J. Smith is a Reader in Earth Sciences at the Open University.

consider the problem ecologically, as one of potential extinction or survival of the group'. Indeed, kuru probably speaks more to this *caveat* than to the basic model, as the disease is now thought to have appeared around 1910 (Burnett & White *Natural History of Infectious Disease,* Cambridge, 1971; Marsh in *Slow Virus Diseases of Animals and Man,* ed. Kimberlin, North–Holland, 1976), and it is hard to see that a group could long sustain a custom with such damaging consequences; during the peak incidence of the disease, in the 1950s, 1% of the Fore population would die of kuru each year, with the prevalence of active kuru reaching 5–10% of the inhabitants of certain tribes (Marsh *op. cit.*).

The authors also show that if any strongly disadvantageous trait can be learned outside the family environment, then a low frequency of the trait may be maintained, in a manner completely analogous to the classical mutation–selection balance of population genetics.

Formidable mathematical difficulties stand in the way of a more full understanding of the interplay between cultural and biological evolutionary processes. As noted by the above authors, and, in a related context, by Oster, Ipaktchi and Rocklin (*Theor. Pop. Biol.* **10,** 365; 1976), by Slatkin (*Proc. natn. Acad. Sci. U.S.A.* **66,** 87; 1970) and by Lande (*Genet. Res. Camb.* **26,** 221; 1975), the general equations relating the gene frequencies in successive generations are not only non-linear, but also involve frequencies from yet earlier generations. The resulting dynamics can have alternate stable points, or a variety of stable cycles, or even apparently chaotic fluctuations that are in many ways indistinguishable from random noise (see the reviews by May *Nature* **261,** 459; 1976; and by May & Oster, *Am. Nat.* **110,** 573; 1976). Nevertheless I believe that the incorporation of cultural inheritance into the quantitative theory of population genetics, as begun by Feldman, Cavalli-Sforza and others, is likely to open exciting new areas. □

Ancient distribution of lime trees in Britain

from Peter D. Moore

Two species of lime tree, *Tilia cordata* and *T. platyphyllos,* together with their hybrid, are native to the British Isles. They are warmth-demanding trees and reach their climatic limits in Britain, neither species occurring naturally in areas with a July mean temperature less than 15 °C. Pigott (*J. Ecol.* **57,** 491; 1969) considers that woodlands containing these species have often been undisturbed over long periods of time, for they frequently contain a characteristic assemblage of plant species which is lost in disturbed woodlands. Interference by man in such woodlands, he claims, often leads to the replacement of lime by ash, elm and sycamore. Such a view was given support by the palynological work of Turner (*New Phytol.* **61,** 328; 1962), who demonstrated the coincidence of the decline in *Tilia* pollen, often in Iron Age times, with evidence of human activity.

Within the British Isles, *Tilia platyphyllos* is the more restricted in its distribution, and both species are generally associated with base rich soils of mull humus type. *T. cordata,* however, does occur on acid, well-drained soils in eastern Europe in association with pine and spruce (Pigott *Phil. Trans. R. Soc.* **270,** 151; 1975).

The past history of the genus in Britain is rather confused for a number of reasons. Identification to specific level has only been undertaken as a routine process in recent years, since Andrew (*New Phytol.* **70,** 683; 1971) showed that exine patterning provides a reliable guide. Subsequent counts in which separation has been effected, such as those at Holme Fen by Godwin and Vishnu-Mittre (*Phil. Trans. R. Soc. Lond.* **270,** 561; 1975) show a strong predominance of *T. cordata* throughout the post-glacial, which corresponds with present-day relative abundance of the two species. Most other published and unpublished data from other parts of Britain confirm this.

Before human interference with woodland became a major factor in the history of our vegetation, say 5,000 years ago, the pollen of lime was distinctly more abundant in southern and eastern England. Birks, Deacon and Peglar (*Proc. R. Soc. Lond.* **B 189,** 87; 1975) have mapped *Tilia* pollen frequencies at that time and show only East Anglia, the east Midlands and the south-eastern extremity of Britain with values of 11–15% of tree pollen. There were times, however, during the height of forest development in this country when lime must have been locally abundant. In East Anglia at Holme Fen, values up to 50% arboreal pollen were recorded, and up to 30% at Old Buckenham Mere (Godwin *New Phytol.* **67,** 95; 1968).

Being insect pollinated, *Tilia* is probably under-represented in aerial pollen fallout, although according to Godwin (*History of the British Flora,* Cambridge University Press; 1975) it produces large quantities of pollen. It is difficult, therefore, to interpret such values in terms of lime abundance in the contemporary woodlands.

It is interesting to note that high *Tilia* proportions have also been recently reported from areas on Cretaceous and Tertiary sands and gravels in the south east. For example, unpublished analyses of J. A. Webb on Hothfield Common, Kent (Lower Greensand) have *Tilia* cf. *cordata* pollen values up to 40% of arboreal pollen. On the northern side of the North Downs from this site, at Wingham, near Canterbury, a value of 20% was obtained by Godwin (*Veröff. geobot. Inst. Zürich* **37,** 83; 1962). In this analyses of Wealden soils, however, Dimbleby has failed to record high *Tilia* pollen levels (see for example, *Proc. Prehist. Soc.* **26,** 246; 1960; **31,** 85; 1965; *Grana Palynol.* **4,** 140; 1963, all sites on the Wealden Lower Greensand). It is interesting to note in passing that one of Dimbleby's sites, Addington in Kent, was the location of the first reliable record for sub-fossil *Tilia platyphyllos* by Burchell and Erdtman (*Nature* **165,** 411; 1950).

On the North side of London, some unpublished analyses of the small valley mires of Epping Forest by P. Oxford have revealed high *Tilia* levels in basal samples. Now, in this issue of *Nature* (page 45), Girling and Grieg have published a pollen diagram from the Bagshot Sands of Hampstead Heath, and they also find high levels of lime pollen (up to 30% of arboreal pollen excluding *Alnus*). The exclusion of *Alnus* from the pollen sum has little effect upon these high *Tilia* levels below 100 cm in depth as *Alnus* abundance is low below this. On the basis of this and other data Girling and Grieg suggest that lime was a dominant tree in southern and eastern England. Locally this may well be the case, but the great variation found from one site to another does indicate that high *Tilia* representation is likely to reflect only local dominance. The isolated records of abundant lime pollen from sites further north and west, such as

Peter D. Moore is a lecturer in the Department of Plant Sciences, Kings College, London.

Shustoke, Warwickshire (Kelly & Osborne *Proc. Linn. Soc. Lond.* **176**, 37; 1965) and west Wales (Smith & Taylor *Trans. Inst. Br. Geogr.* **48**, 75; 1969) show that there may have been local pockets of lime dominance outside the south east of England. But until more data is available from southerly sites the extent of lime dominance will remain an area of speculation. Results such as those of Girling and Greig make it evident that many sandy areas in the south east which now bear heathland were once covered by forest at least locally rich in lime. ☐

Amyloidosis, P component and complement

from A. H. Gordon

AMYLOIDOSIS is the pathological deposition of glycoprotein-like material in body tissues. Various genetically different types of the disease have been identified, in which the major amyloid component and the sites of deposition differ. In primary amyloidosis (in which there is no obvious predisposing condition) immunoglobulins are apparently the main constituent of amyloid fibrils. In secondary amyloidosis, which is often a complication of chronic destructive infections such as tuberculosis and leprosy, the fibrillar AA protein deposits are immunologically similar to one particular plasma protein, SAA, (also found in normal sera) synthesised by B cells. Recent work on the analysis of amyloid tissue deposits has also revealed close amino acid sequence similarities between P component, present as a minor component in all forms of the disease and the recently discovered C1t, the fourth constituent of the first component of complement (C1). A more distant but definite sequence homology has also been demonstrated between P component and CRP (C-creative protein) (Levo *et al.* this issue of *Nature* page 56), a plasma protein which can interact with pneumococcal C-polysachharide, choline phosphate and various polycations to activate the complement cascade. Although a great deal is now known about amyloid components, the factors which cause amyloid deposition are still unclear.

In secondary amyloidosis for example, the concentrations of many plasma proteins, especially the so-called 'acute phase' proteins are increased, SAA among them. Acute phase proteins are those which are found in the serum in increased concentrations after any injury or shock. Amyloidosis can be induced in susceptible strains of mice by repeated injections of casein or lipopolysaccharide but McAdam and Sipe have shown that although injection of a single dose of bacterial lipopolysaccharide or casein (B lymphocyte mitogens) in mice leads to greatly increased concentrations of SAA in the plasma, this does not always lead to amyloidosis (*J. exp. Med.* **144**, 1121; 1976). They consider that in this case the difference between amyloid-prone and resistant mice is likely to be found in the lysosomes. According to this view the amyloid-prone mice are considered to suffer from a catabolic defect in protein degradation.

An interesting difference between SAA obtained from amyloid and non-amyloid human plasma has also been reported by Sipe *et al.* (*Br. J. exp. Path.* **57**, 582; 1976). This concerns the β-pleated sheet conformation which renders the protein of the fibrils insoluble. The difference relates to the dissociation in guanidine HCl or formic acid of SAA of molecular weight 160,000 to SAAL (molecular weight 12,500). In the same conditions SAA from amyloid plasma dissociated less, and reaggregated more readily, than SAA from normal plasma.

Because the increased concentration of SAA which occurs in these conditions will be accompanied by increased concentrations of a number of other plasma proteins, it is necessary to consider how far increased concentrations of other acute phase plasma proteins may predispose towards amyloidosis. In rabbits and humans the acute phase protein which increases most is CRP. As mentioned above, this protein shows partial amino acid homology with the P component of amyloid which is itself homologous with C1t. CRP, P component and C1t all complex strongly with Ca^{2+}. Furthermore, in inflammatory conditions the opportunity exists for CRP to complex with a number of cationic and/or anionic products of a cell breakdown or, indeed, with C-polysaccharide itself.

Such complexes act very similarly to antigen–antibody complexes in that they bind to C1 and initiate the consumption of complement. Perhaps the most surprising fact to emerge from the structural studies is the extensive homology between CRP, which itself is an activator of C1, and C1t, one of the subcomponents of C1. Since both CRP and C1t react with C1q they may in some manner modulate each others actions. This may affect the availability of P component and thus the likelihood of amyloid deposition.

These structural relationships, if seen from the evolutionary standpoint, take on a wider immunological significance. Also important in this regard is a further homology recently shown to exist by Osmand, Gewurz and Friedenson (*Proc. natn. Acad. Sci. U.S.A.* **74**, 1214; 1977) between CRP and the immunoglobulins. Comparison of the sequences of CRP and the C_H3 domain of human IgG has indicated a distant but significant homology. Using in addition data for C1t, the times since divergence of CRP and C1t have been calculated to be 2×10^8 yr, and more than 5×10^8 yr, for the earlier divergence of CRP from the immunoglobulins. The structural relationship now apparent between CRP and the immunoglobulins might perhaps have been expected in view of the similarity of function of antibody–antigen complexes and CRP when complexed with C-polysaccharide or another polyanion or polycation. These include the ability to stimulate phagocytosis and act both as agglutinin and opsonin. Particularly relevant to amyloidosis, however, is the activation of complement by both antigen–antibody complexes and CRP in complex form. Certainly long before divergence of CRP and C1t took place the parent molecule which may be presumed to have already had the power to bind Ca^{2+} would have been available as a constituent of amyloid.

Further evidence for the formation of amyloid from α_2 globulins of mouse plasma has been obtained by Kisilevsky *et al.* (*Am. J. Path.* **83**, 299; 1976). In this work with ^{125}I-labelled mouse plasma proteins, rates of synthesis and degradation of albumin α_1, α_2, β and γ globulins were measured for groups of mice receiving azocasein (AC) and amyloid-enhancing factor (AEF) obtained from the spleens of mice previously treated with AC. Amyloid was found only in the group which had received AC and AEF. However, both this group and that which had received AC only, showed significant increases in the turnover rate of α_2 globulin, $t^{1/2}$s 73% and 79% respectively, compared with the control group. This increased turnover of α_2 globulin by both groups can be reconciled with the appearance of amyloid in the AC+AEF group only, on the assumption that amyloid deposition occurs by removal of partially degraded material and that this process is without effect

---

A. H. Gordon is a member of the scientific staff of the National Institute for Medical Research, London.

on the turnover rate. On the basis of these experiments Kisilevsky has attempted a generalisation as to the mechanism underlying amyloid deposition. In his view the precursors of amyloid are *l*-chains in myeloma-associated amyloid and α_2-globulin when the disease is secondary to an inflammatory state.

In such conditions an increased load of glycoproteins, which will be accounted for largely by the increased concentrations of SAA, will be taken up by the reticuloendothelial system (RES). If the RES is overloaded or functioning less than optimally, as for instance after treatment with BCG, degradation of α_2 globulins, and in particular SAA, will not go to completion. Thus, subunits will then accumulate and in due course will combine to form fibrils. However, for this to happen certain additional conditions are likely to be necessary. Since the partial breakdown of the SAA protein or other glycoproteins will occur in the lysosomes differences in respect to lysosomal enzymes are likely to be important. The existence of genetic differences in respect to amyloidosis has already been mentioned. Minor genetically-determined structural differences may perhaps be responsible for the enhanced tendency to associate as amyloid fibrils shown by the SAA obtained from amyloid plasma. ☐

Terminal redundancy in avian oncornavirus RNA

from T. J. R. Harris

THE avian oncornaviruses provide a good model for analysing the *modus operandi* of the Retroviridae. Viruses in this family make a DNA copy of their single stranded genome RNA using the RNA-dependent DNA polymerase (reverse transcriptase) packaged in the virus particle. This complementary DNA (cDNA) is then copied into a circular double-stranded DNA molecule which can integrate into the host cell DNA. Studies *in vitro* with reverse transcriptase are now beginning to unravel the possible molecular mechanisms behind this interesting sequence of events and to explain how the circular DNA molecules might be formed.

The primer required by reverse transcriptase for the initiation of synthesis is one of the host cell transfer RNA molecules associated with the genome RNA and making up the 70S complex in the virus. For both Rous sarcoma virus (RSV) and avian myeloblastosis virus (AMV), the tRNA specific for tryptophan is the one used. As cDNA synthesis proceeds in a 5′–3′ direction one might expect that the primer would be bound at the 3′ end of the RNA. Surprisingly, however, Taylor & Illmensee in a concise paper (*J. Virol.* **16,** 553; 1975) showed for RSV RNA that the primer was in fact bound near the 5′ end of the RNA—a finding since confirmed for AMV RNA (Stakus *et al. Virology* **71,** 162; 1976). Collett & Faras (*Proc. natn. Acad. Sci. U.S.A.* **73,** 1329; 1976) analysed the cDNA produced by the AMV enzyme and found that molecules containing sequences complementary to the 5′ end of the virus RNA also contained sequences complementary to the 3′ end. These observations led the authors to suggest that some of the sequence at the 5′ end of the virus RNA was repeated at the 3′ end providing both virus RNA and cDNA with the capacity to form circles. Direct evidence has now been obtained from sequencing studies to support this suggestion. Haseltine, Gilbert & Maxam (*Proc. natn. Acad. Sci. U.S.A.* **74,** 989; 1977) have sequenced the 101 nucleotides of tRNA^{Trp}-primed cDNA complementary to the 5′ end of the virus RNA using their rapid DNA sequencing technique, while Schwartz, Zamecnik & Weith (*Proc. natn. Acad. Sci. U.S.A.* **74,** 989; 1977) used oligo(dT)-primed reverse transcription followed by partial exonuclease digestion of the product to obtain a short sequence adjacent to the poly(A) at the 3′ end of the virus RNA. The first 21 nucleotides of RSV RNA after the capping group were found to be identical to the 21 before the poly(A). Haseltine *et al.* discuss in detail the implications of the terminal redundancy for circle formation and formation of provirus DNA and some evidence for the circular structures they envisage is accumulating from heteroduplex analysis of RNA/cDNA hybrids (see Junghans *et al. Proc. natn. Acad. Sci. U.S.A.* **74,** 477; 1977). Also, knowledge of the 5′ cDNA sequence enabled Haseltine *et al.* to construct plausible models of the possible ways that the 5′ ends of the two genome RNA molecules and their tRNA primers might be associated in the virus particle as the 70S complex.

The advent of the fast and accurate nucleic acid sequencing methods should enable more of the cDNA sequence to be determined (as well as that of the dsDNA and its precursor molecules) so that some of these speculations can be tested. One must add the proviso however that any mechanism of synthesis outlined from *in vitro* studies may not necessarily be the same as that actually occurring *in vivo*. Nevertheless, sequencing the parts of the RNA (by way of cDNA) coding for the structural and non-structural polypeptides will inevitably lead to a greater understanding of the replication of this important family of oncogenic viruses.

Anoxic events in the Cretaceous ocean

from A. Hallam

THAT the Black Sea is stagnant in its deeper part is a widely known and comparatively well understood fact. Freshwater runoff from the surrounding land promotes salinity and hence density layering which is not destroyed by convective overturn because of restriction on interchange with Mediterranean waters by the sill of the Bosphorus. The surface waters contain free oxygen because of photosynthetic activity and exchange with the atmosphere, but at greater depth an anaerobic condition is produced as oxygen is consumed by organisms and replaced by hydrogen sulphide, the by-product of the metabolic activity of sulphate-reducing bacteria. In consequence the bottom sediments are rich in unoxidised bituminous matter derived both from terrestrial plants and phytoplankton, together with iron sulphide. They are also finely laminated because no benthonic organisms can survive in the anoxic environment and the sediment is not churned over by burrowers. Because of the name by which the Black Sea was known in the classical world, such sediments and environments are known as euxinic, and a Black Sea-type 'barred basin' model has been widely applied by geologists to account for the formation of finely laminated marine bituminous shales.

In marked contrast to the rather unusual Black Sea situation, the floor of the open ocean is well oxygenated,

---

A. Hallam is Professor of Geology in the University of Birmingham.

with powerful currents and water renewal operating even at great depth. It has therefore come as one of the great surprises of the Deep Sea Drilling Project that, at several horizons within the Cretaceous, bituminous sediments comparable with those of the Black Sea have been discovered beneath the Atlantic, Indian and Pacific oceans, with an organic carbon content as high as 28%. In the case of the earliest discoveries in the Atlantic, research workers initially proposed a Black Sea model, with stagnant basins in a much smaller ocean possessing only restricted connections with the larger ocean system. Now that it is known that such organic-rich deposits are much more widespread, and occur also on topographic rises in the Pacific, such an interpretation must be abandoned.

A number of recent papers is devoted partly or entirely to the problems posed by these deposits (Ryan & Cita *Mar. Geol.* **23,** 197; 1977: Schlanger & Jenkyns *Geol. Mijnb.* **55,** 179; 1976: Fischer & Arthur, *Soc. Econ. Min Paleont, Spec. Publ.* 25, in the press). On one major point all the authors are in agreement. The Cretaceous world ocean must have been in a very different state from that of today, with a considerably expanded oxygen minimum zone. The oxygen content in the modern ocean diminishes rapidly downwards in quite shallow water, but increases again in the depths. This pattern relates to strong circulation of cold and dense bottom waters from surface water at the poles and is therefore ultimately bound up with climate. In more equable periods in the past such as the Cretaceous, with no polar ice caps, oceanic circulation would have been much more sluggish, with a far lower rate of renewal of bottom waters.

Beyond this, the authors diverge in their treatment, though not necessarily in a mutually contradictory way. Ryan and Cita cite four principal horizons where extensive organic-rich sapropels have accumulated, in the latest Barremian, Aptian, mid-Cenomanian and latest Coniacian stages, and calculate that they contain an order of magnitude more carbon than is present in all the known reserves of coal and petroleum. They therefore form an enormous sink for carbon and also sulphur (because of the abstraction of iron sulphide). Ryan and Cita argue for significant increase, in consequence, in the amount of atmospheric oxygen. Schlanger and Jenkyns single out Aptian–Albian and Cenomanian–Turonian boundary beds as being especially important, and point to similar bituminous deposits occurring at these horizons also in quite shallow water deposits on the continents. They attribute these unusual and evidently extremely widespread occurrences to eustatic rises of sea level in a more equable world with a wider tropical belt than at present, with in consequence much higher organic productivity both on land and in the sea, and infer a pronounced oxygen minimum layer which reaches up to less than 300 m and down to 2,000–3,000 m below sea level.

For Fischer and Arthur, the Cretaceous bituminous deposits are an important component of an ambitious and imaginative hypothesis, which distinguishes a series of polytaxic and oligotaxic episodes extending back to the Jurassic with a 32 Myr cycle. Their polytaxic episodes are characterised by high organic diversity, higher and more uniform oceanic temperatures, eustatic rise of sea level, widespread marine anaerobism and undisturbed marine sedimentation, together with heavier carbon isotopes in organic matter. Oligotaxic episodes including the present day, exhibit, in contrast, lowered organic diversity, low sea level, sharper lateral and vertical temperature gradients in the oceans because of stronger circulation, more disturbed and aerobic sedimentation and lighter carbon isotopes. The fundamental controls are seen as climate and relative height of sea level.

To establish a 32 Myr cycle Fischer and Arthur seem to be guilty in some cases of pushing the evidence beyond reasonable limits. For example, they are obliged to stress the importance of the Albian bituminous horizon at the expense of the others, and choose to ignore the fact that in north-east England the stage is developed in red chalk facies, one of their markers for oligotaxic episodes. Furthermore, the Tertiary bituminous occurrences they cite are much less well established in the oceans than those of the Cretaceous. While there are indeed some striking correlations between diversity, sea level and isotope abundances in the Tertiary, the evidence presented for the Jurassic looks decidedly unconvincing. Nevertheless these reservations should not be held seriously to detract from a highly stimulating and thought-provoking work, which ought to be read by those interested in ocean history. □

New interest in carbon lamellar compounds

from A. R. Ubbelohde

A Conference on Carbon Lamellar Compounds was held at Napoule, near Cannes, on 23–27 May 1977. It was jointly organised by Professor A. Herold, Department of Applied Mineral Chemistry of the University of Nancy, and Professor F. Vogel, Moore School of Electrical Engineering of the University of Pennsylvania at Philadelphia. The Conference Proceedings will be published as a special issue of the *Journal of Materials Science and Engineering,* which will be obtainable separately. This article aims to stress some of the more striking information presented and discussed.

WAVES of innovative international research on graphites have passed through at least two previous maxima. The first wave was powered by interest in uses of graphite in nuclear energy generation. Gradually this has tapered to an asymptote, with the realisation that such uses have foreseeable limitations. A second wave was associated with the brilliant promise of carbon fibres for the aircraft industry. Following a spectacular setback, slow recovery of research and development on carbon fibres is under way. Though at present rather humdrum, and prompted by applications of carbon fibres to golf clubs and fishing rods, such background research seems likely to grow steadily.

A third wave of very active innovative research on graphites has formed internationally in recent years. It concerns the remarkable properties of their lamellar compounds. These are formed by intercalation of a great variety of molecules between the carbon hexagon layers in graphite, after these have been separated sufficiently for the intercalate species to enter and lie between them. Although the conference reported here dealt predominantly with graphite componds, other layer crystals such as MoS_2 show analogous behaviour. From a chemical standpoint, intercalates can broadly be grouped as electron donors, such as the alkali metals Li, (Na) K, Rb and Cs, and electron acceptors such as Br_2, ICl, inorganic halides, and a number of other types. There is also an important group of carbon lamellar

---

A. R. Ubbelohde is Emeritus Professor of Thermodynamics and Senior Research Fellow in the Department of Chemical Engineering and Chemical Technology, Imperial College, London.

compounds such as graphite bisulphate $C_{24}^{+}HSO_4^{-}2H_2SO_4$, formed by electrochemical (or the equivalent chemical) oxidation in the presence of the appropriate acid molecules.

Synthetic metals

One basic reason for the current widespread interest in lamellar compounds stems from the fact that in these the partner molecules form charge transfer bonds with the carbon hexagon networks, which act as giant aromatic molecules in this respect. Such charge transfer bonding was first postulated some 25 years ago (McDonnell *et al. J. chem. Soc.* 191; 1951). Many examples have now been studied. The striking growth of research on these compounds seems to be due to their interest and promise as synthetic metallic conductors. Intercalate molecules in carbon lamellar compounds also show distinctive chemical behaviour as catalysts, and in other ways. Means of making various precise physical and optical measurements have become more refined in recent years, so that much more precise information is beginning to be available to help interpret the nature and properties of the charge transfer bands formed. Nearly one-third of some 60 papers discussed during the meeting dealt with this aspect. Practically all the advances described were very recent. Surprising new facts and novel theoretical arguments kept members of the conference in a ferment throughout.

Inorganic chemistry

Experimental methods were described for introducing intercalate species not hitherto known to form lamellar compounds, for example by the use of oxidising agents such as $C_6F_6AsF_6$ (N. Bartlett, Lawrence Berkeley Laboratory, University of California, Berkeley) or catalysts such as $Co(AlCl_4)_2$ (E. Stumpp, Technical University at Klausthal-Zellerfeld). Production of C_8Li by interdiffusion of the powdered solid elements (Herold) is also a recent innovation in the use of Li as an electron donor intercalate. Formation of ternary lamellar compounds by intercalation of a second partner into binary lamellar compounds often occurs rather unexpectedly. Different instances described by several authors included the intercalation of molecular H_2, of tetrahydrofurane, of benzene, or of other molecules into lamellar compounds with alkali metals. Apart from any effects on the local charge transfer bonds, such ternary intercalation usually pushes apart even further the carbon hexagon layers from their initial separation of 3.35 Å in graphite. This 'layer dissociation' may have important consequences for electrical and other properties of carbon lamellar compounds.

Solid-state physics

Clarification of physical properties of various lamellar compounds of graphite was discussed. There have been elegant advances in band theory and important information has been obtained by precision measurements of various optical properties. For example, it now seems clear from infrared and Raman spectra that the fractional charge transfer when molecular Br_2 is intercalated is only a few tenths of one percent (G. Dresselhaus and M. S. Dresselhaus, Massachusetts Institute of Technology). Graphite/bromine was one of the first lamellar compounds for which a remarkable increase of metallic properties occurs on intercalation (McDonnell *et al. op. cit.*) and the rise in electrical conductivity begins steeply as the first few molecules of bromine enter the graphite. This recent optical work suggests (A. R. Ubbelohde, Imperial College, London) that metallic conduction in the halogen lamellar compounds resulting from charge transfer involves only relatively few additional charge carriers, but if so these must have exceptionally large mobilities.

Quite generally, under suitable conditions, synthetic metals formed by charge transfer in lamellar compounds of graphite seem to exhibit exceptionally low scattering of charge carriers travelling in the directions of the layer planes. This points to a two-dimensional mode of conduction which differs at least quantitatively and perhaps also qualitatively from that in the familiar three-dimensional metals (Ubbelohde). Such findings stress the importance of making many more measurements on the anisotropy of various physical properties parallel and perpendicular to the layer planes. Remarkably, very few *c*-axis measurements on lamellar compounds were presented to this conference, but there seems every hope that this gap will before long be filled.

A hundred years ago

THE application of new materials for paper stock which has occupied so much attention of late seems to have attracted some notice in the Philadelphia Exhibition last year. From Jamaica bamboo was perhaps the most important paper-making plant exhibited. Of the young bamboo stems, which are the best for the purpose, a very large supply, it is said, could be annually, by systematic cuttings or croppings, furnished from plants flourishing in the humid parts of the island.

Ramsey fringes in optical spectroscopy

from Robin M. Hochstrasser

EXPERIMENTS have been reported recently in which the spectral resolution in optical spectroscopy of gases can be limited only by the time of flight difference between two light pulses. Limitations due to Doppler broadening, the homogeneous width of the resonant state, or the transform spectral width of the laser pulse, have been eliminated.

The Doppler broadening of a spectral line at ω_{ba} can be eliminated if the transition $a \rightarrow b$ is brought about by the simultaneous absorption of two photons, one from each of two counter-propagating beams having frequency $\omega_{ba}/2$. This type of non-linear spectroscopy requires high light power so that present day laser beams must be sharply focused in order for the signals to become readily detectable. With high peak power pulsed lasers such as a nitrogen-pumped dye laser some focusing of the beam is still necessary to observe these non-linear effects.

A severe limitation of pulsed dye lasers in high resolution spectroscopy is that typical pulses have a duration of 8 ns corresponding to a minimum frequency uncertainty of ~ 125 MHz for transitions occurring during the transit of such a pulse. For molecules travelling at 10^3 m s^{-1} across a laser beam focused to a diameter of 10^{-4} m the accuracy of the experiment is not limited by the transverse transit time which contributes only ~ 10 MHz to the spectral width. Transit time limitations on spectral accuracy have been known for a long time in beam resonance spectroscopy and in 1949 N. F. Ramsey (*Molecular Beams*, Ch V, Oxford University Press, 1956) suggested his method of separated oscillating fields in order to overcome this difficulty. In Ramsey's method the molecular beam passes through an RF field region of length l in time τ, and then travels a distance L before reaching a second identical RF field region. The number of transitions at a fixed RF frequency undergone in such a spectrometer is an oscillatory function of the time L/v, where v is the most probable velocity of molecules

---

Robin M. Hochstrasser is Professor of Chemistry at the University of Pennsylvania.

in the beam. In the intermediate region the separate components of the non-stationary state produced by the first RF region each evolve like stationary states for a time L/v so that the wavefunction is changed from

$$\psi(\tau) = \{a(\tau)\varphi_a + b(\tau)\varphi_b\}$$

into

$$\psi(\tau + L/v) = \{a(\tau)e^{-i\omega_a L/v}\varphi_a + b(\tau)e^{-i\omega_a L/v}\varphi_b\}.$$

The oscillations, or Ramsey fringes as they are now termed, arise because the probability of transitions in the second RF region is proportional to:

$$|A(\tau)\sin\{(\omega_{ba} - \omega)L/2v\} + B(\tau)\cos\{(\omega_{ba} - \omega)L/2v\}|^2,$$

which corresponds to an interference pattern. The fringes are separated by $V/2L$ whereas the spectra from only one RF region have widths of ~ $1/\tau$, so that the method of separated fields improves the sharpness of the spectral lines by a factor of ~ L/l.

In the paper by Salour and Cohen-Tannoudji (*Phys. Rev. Lett.* **38,** 757; 1977) an analogue of the Ramsey fringes was observed in the optical region. Whereas with the RF field it is easy to have two regions excited coherently during the whole experiment, it is rather difficult to accomplish this with optical fields. Instead, Salour and Cohen-Tannoudji generated two pulses in an optical delay line starting with a pulse obtained by amplifying a cw wave in a series of synchronously pulsed dye laser amplifiers. The two phase-locked pulses, separated by a distance L, were focused into a cell containing sodium vapour behind which was a mirror to reflect the beams back through the sample. The vapour was thereby subjected to a standing wave optical field of two pulses each of width τ separated by $T = L/c$. There is no Doppler shift for two-photon transitions in the standing wavefield. A photomultiplier detected the 90° fluorescence that occurs after two-photon absorption by Na atoms. The two-photon excitation spectrum of the $3^2 S \rightarrow 4^2 D$ transition, obtained by scanning the laser and detecting the fluorescence, showed not only the hyperfine structure, but each hyperfine component displayed Ramsey type fringes separated by as little as 30 MHz for $2T = 33$ ns.

Teets *et al.* (*Phys. Rev. Lett.* **38,** 760; 1977) also investigated the Doppler-free two-photon spectrum of sodium using a train of phase coherent pulses generated by multiple reflections of a dye laser pulse in a resonator containing the sample. The two photon signal was measured as a function of resonator tuning and a Fabry-Perot type spectrum was obtained with line-widths of about 12 MHz using a 2-m confocal resonator.

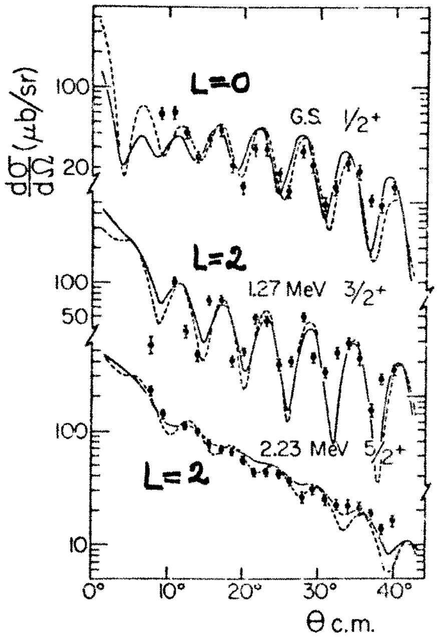
Although these experiments are expensive and not uncomplicated, especially in regard to the problem of maintaining a constant phase difference between the laser pulses, their success opens up important new possibilities for the study of molecular excited states at MHz resolution. ☐

Heavy ion transfer reactions

from P. E. Hodgson

THERE have been many studies of reactions between heavy ions in which one or more nucleons are transferred, and it is usually found that the cross section can be accounted for quite well by the distorted wave theory. In some cases it is found that the cross sections are more sensitive to particular aspects of nuclear structure than the corresponding reactions with light projectiles, and this makes them useful tools in nuclear spectroscopy.

An example of this is the spin-dependent effects in some transfer reactions. If a particle is transferred from a (l_2, j_2) state in the projectile to a (l_1, j_1) state in the residual nucleus the angular momentum selection rules allow several values of the transferred angular momentum L, and these depend on whether the angular momentum given to the residual nucleus is $j_1 = l_1 + \frac{1}{2}$ or $j_1 = l_1 - \frac{1}{2}$. In the particular case when $l_2 = 0$, then $L = l_1$ and it is possible to study the dependence of the cross section on j_1 for a given value of L.



Differential cross section for the reaction ^{28}Si(^{19}F, ^{16}O)^{31}P at 60 MeV to three states in ^{31}P compared with normalised distorted wave calculations including a spin-orbit potential in the incident and exit channels. The dashed curves show the effect of including inelastic excitations.

Such a study has recently been carried out by a group at the University of Minnesota for the ^{28}Si(^{19}F,^{16}O)^{31}P reaction at 60 MeV (*Phys. Rev. Lett.* **38,** 817; 1977). In this reaction three nucleons are transferred, but it is a good approximation to consider these as a triton-like cluster and thus retain the simplicity of a one-nucleon transfer reaction. This is likely to be quite a good approximation since 92% of the ^{19}F wavefunction can be expressed as a cluster of three particles in a relative 1s state moving with angular momentum $l_2 = 0$ with respect to the ^{16}O core. The experimental cross sections for the $L = 2$ transfers to the lowest $\frac{3}{2}^+$ and $\frac{5}{2}^+$ states in ^{31}P are shown in the figure; these differ markedly and show how the reaction can depend on j as well as on L. The cross section for the $L = 0$ reaction to the $\frac{1}{2}^+$ ground state is also shown.

The first distorted wave calculations, made with a finite range interaction and taking recoil into account, did not give a satisfactory fit to the data, and there was no appreciable improvement when inelastic excitation of the projectile was included by making a full coupled-channels calculation. The satisfactory fit shown in the figure was obtained when spin-orbit potentials were included in the distorting potentials in the incident and exit channels. Once again the fit was very little affected by the inclusion of inelastic excitations.

This work shows that the pronounced j-dependent effects in three-nucleon transfer reactions can be accounted for using the distorted wave theory provided spin-orbit potentials are included in the distorting potentials. It also provides striking confirmation of the validity of the cluster transfer approximation and shows that in this case inelastic excitations are relatively unimportant.

Further studies of similar reactions will be needed to confirm that the essential physics of the reaction has indeed been well understood, and if this is the case then the reaction, and others like it, should prove to be a powerful spectroscopic tool for determining the spins of the final states in the residual nuclei. ☐

P. E. Hodgson is Lecturer in Nuclear Physics in the University of Oxford.

review article

Energy production by microbial photosynthesis

John R. Benemann*, Joseph C. Weissman, Ben L. Koopman & William J. Oswald

The large amounts of microalgae produced in waste treatment ponds during sewage purification are a potential source of methane and fertiliser. If techniques can be developed for the selective cultivation of filamentous or colonial microalgae, harvesting of microalgal biomass could be accomplished by low-cost straining or sedimentation methods.

INCREASING public and governmental awareness of the serious problems of energy and environment faced by most of the nations of the world is resulting in reappraisals of all potential energy sources. Evaluations of the various energy alternatives must consider, together with technical and economic factors, their environmental and social impact. Here we review the scientific and practical aspects of fuel and fertiliser production from microalgae and photosynthetic bacteria.

Bioconversion

Until less than a century ago, photosynthesis provided over 90% of mankind's fuels[1]. Even today, on a worldwide basis, the total calorific value of primary photosynthetic production (plant biomass) used by mankind is higher than that of the fossil energy consumed[2]. Only in the industrialised nations with temperate climates are fossil fuels more important than current photosynthetic biomass production in such a comparison. At present, over one-half of the people in the world depend on wood and dung for the majority of their fuels. The diminishing availability of these biofuels to the poorer half of the Earth's population is a more serious and immediate energy crisis than depletion or monopolistic control of fossil fuels.

Photosynthesis can provide a larger share of mankind's fuel needs through (1) shifts in relative usage (such as conversion of organic wastes to fuels or reduction in luxury consumption levels of animal protein) or (2) by increasing plant biomass production for direct utilisation or conversion to fuels. The potential of plant biomass production for the exclusive or primary purpose of fuel production is, in practice, limited by a number of constraints—the relatively low efficiency of photosynthesis in solar energy conversion; competition with agriculture or forestry for land, water and fertiliser; marginal economics of biomass production and conversion into usable energy; need for low-energy cultivation technology; and a lack of experience with such processes, and so on. Because most inputs in a bioconversion system would be constant per unit area, the net productivity (expressed as incident solar energy conversion efficiency) is a critical parameter since it must be sufficiently high to justify all costs.

Photosynthesis is limited by its dependence on visible light (about 45% of total solar radiation), reflectance losses (10–20%), a quantum efficiency of only 25%, and metabolic losses, giving a value of 5–6% for the theoretical maximum solar energy conversion efficiency[3-7]. In normal field conditions, photosynthesis rarely approaches the theoretical limit which applies only in light-limiting conditions. Sustained year-round, solar conversion efficiences exceeding 1% are unusual in agriculture. In addition, such high yields are often dependent on high fossil fuel subsidies or large human labour inputs, thus reducing the net efficiencies realised. Very high productivities (above 1% efficiency) with favourable net energy ratios are possible only with a few highly productive plants such as sugar cane[8]. The limitations to bioconversion suggest that practical applications will require utilisation either of the most efficient agricultural crops (for example sugar cane) or less efficient but more hardy plants capable of being cultivated in marginal areas with few inputs. The list of plants considered for biomass production is already large; they may be classified as either dry land or aquatic. The aquatic plants may, in turn, be classified as macro (water hyacinths, seaweeds, and so on) and micro (unicellular or small colonial algae and photosynthetic bacteria). We shall consider only the microscopic aquatic plants—microalgae and photosynthetic bacteria—and their potential in bioconversion to fuels, fertilisers, and petrochemical substitutes.

Microalgae in waste treatment

Large scale cultures of microscopic algae have been actively investigated for over twenty-five years[9]. Because of the high protein content of algae and the presumed large potential yields, algal research has emphasised protein production. However, practical applications of algal cultures for food or feed production are limited by high capital costs, moderate yields, poor product quality control, and lack of markets. At present, commercial production is limited to a one-ton-per-day pilot plant in Mexico producing *Spirulina* (a filamentous blue-green alga)[10] and several smaller operations in the Far East which produce *Chlorella*.

The development of large-scale algal ponds for domestic and industrial liquid waste treatment has been much more successful[11]. Although originally used only to hold wastes, ponds were observed to substantially reduce pollution indicators–biochemical oxygen demand, odour, and settleable solids. This turned out to be because pond algae photosynthetically generate enough oxygen to allow bacterial oxida-

---

*Sanitary Engineering Research Laboratory, University of California, Berkeley, California.

tion or organic wastes[12]. The released nutrients (carbon dioxide, ammonia, phosphate, etc) are in turn converted into algal biomass. Design equations have been developed to relate pond area requirements to sewage strength and flows, as well as local solar insolation and climatic conditions[13]. This engineering research has resulted in the widespread adoption of algal ponds (known as 'oxidation ponds') in many countries, including the United States, Australia, Israel, South Africa, and India.

Almost all presently used oxidation ponds are the 'facultative' type—one to three metres in depth and arranged in cells of up to 50 hectares, and mixed only by wind action and perhaps recirculation of effluent. The bottom of these ponds are thus anoxic, resulting in fermentation of the settled sludge and algae, while the surface is kept aerobic by the algae, preventing odours from developing (a prime consideration in sewage treatment). The liquid detention time (days required to displace one pond volume) is long, from weeks to months. This design is optimal for waste treatment but not for algal growth. If algal biomass production is to be maximised, the ponds must be shallow (30–50 cm), have short detention times (2–4 days in summer), and be mechanically mixed (to minimise algal settling and prevent thermal stratification). These types of ponds termed 'high-rate', are much more efficient solar energy converters and can be very effective in waste treatment, provided that the algae are removed before discharge of the pond effluent.

The high algal concentrations in pond effluents represent a load of organic matter and nutrients which are regarded by regulating agencies as environmentally undesirable. High-rate ponds produce well above $100\ \mathrm{mg\ l^{-1}}$ of algae (dry weight) and even facultative ponds normally have effluents of above $50\ \mathrm{mg^{-1}}$. These levels of suspended solids are higher than those allowed by present US waste treatment plant discharge regulations; thus, algae must now be removed from oxidation pond effluents. This step is, of course, also required for conversion of algal biomass into usable fuels.

Microalgal harvesting

Concentrating (at least 100-fold) a dilute suspension of microscopic algae is a considerable engineering problem[14,15]. Most oxidation pond algae are below $20\ \mu\mathrm{m}$ in diameter, too small for low-cost straining, filtration, or sedimentation. Only the more expensive centrifugation and chemical flocculation reliably remove algae from pond effluents. Centrifugation requires high capital investments in large centrifuges as well as power to run them. Chemical flocculation is somewhat more cost-effective and is being installed in a few large scale oxidation pond systems in the US, but the weight of chemicals (alum, lime or polyelectrolytes) required often surpasses that of the algae harvested. The flocculated algae are collected either by sedimentation or flotation and expensive extraction steps are then needed before the algae can be used for bioconversion. Furthermore, the chemical–algal sludge is difficult to dewater and dispose of. Thus, high capital and operational costs make chemical flocculation unsuitable for bioconversion systems. Less expensive methods of removing algae from effluents are to settle them in the pond by chemical flocculation, or by prolonged (2–3-week) isolation of ponds from further sewage flows. These methods, although economical, are not suitable for algal biomass production since the algae settle on the pond bottom as a thin layer of sludge which slowly decomposes.

Water reservoirs often exhibit blooms of algae which impart foul tastes and odours to the water and which are removed by large scale 'micro-strainers'. Almost all such algae occur as long filaments or large colonies, which accounts for the effectiveness of microstrainers—rotating straining devices (Fig. 1)—in the purification of reservoir waters. Oxidation pond algae, on the other hand, tend to occur as unicellular or small colonial types, generally under $20\ \mu\mathrm{m}$ in any one dimension, which are too small to be effectively strained. Only the sixth and seventh most common algae in oxidation ponds—the filamentous blue-green alga *Oscillatoria* and the colonial spined green alga *Micractinium*[16], can easily be harvested by microstrainers. If such types of algae were normally prevalent in high-rate oxidation ponds, microalgal harvesting would no longer be a limiting economic factor in algal biomass production from liquid wastes.

Algal population dynamics

Control of algal species in ponds (whether for biomass harvesting, aquaculture, or protein production), must be based on an understanding of the specific factors affecting algal population dynamics. The following are a few generalisations about the importance of various factors. When high strength wastes (for example, food processing wastes) are serially diluted, inoculated, and incubated in the light, different biotypes will appear in the various dilutions. The most concentrated wastes will contain only anaerobic fermentative bacteria. Photosynthetic bacteria appear in the first dilution followed by a graduation of flagellated euglenoids, blue-green algae, green algae, and finally diatoms and nitrogen-fixing blue-green algae. Such successions can also be seen in outdoor ponds going from heavily loaded anaerobic ponds to the final 'polishing' or 'tertiary' ponds. Often, only one or two algal species comprise over 95% of the algal biomass in sewage ponds that are not allowed to fully stabilise (through fast dilution and heavy organic loading). A greater number of algal species is found in the more lightly loaded tertiary ponds, indicating greater stabilisation of the wastes and algal populations. The filamentous blue-green alga *Oscillatoria* is usually found at higher temperatures (being the predominant algae reported from Indian oxidation ponds) and in ponds receiving wastes low in nitrogen (such as cannery wastes). The many environmental, biological, operational and even historical factors which affect algal population dynamics in ponds interact in many ways, complicating the task of understanding algal population dynamics. For example, is is known how seeding of ponds with algae from operating oxidation ponds will affect the establishment and subsequent history of algae in the ponds. In outdoor systems, it is not possible to achieve a steady state due to constantly changing environmental conditions. Temperature, for example, is an important factor in algal successions[17]. The greatest problem is the lack of detailed ecological or limnological data from operating oxidation ponds. The low species diversities and rapid succession of the predominant algal species in ponds indicate a versatile system which can be affected by many environmental conditions.

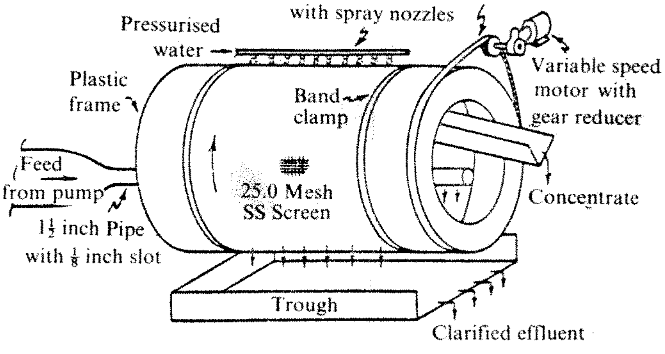


Fig. 1 Small-scale microstrainer

R 394

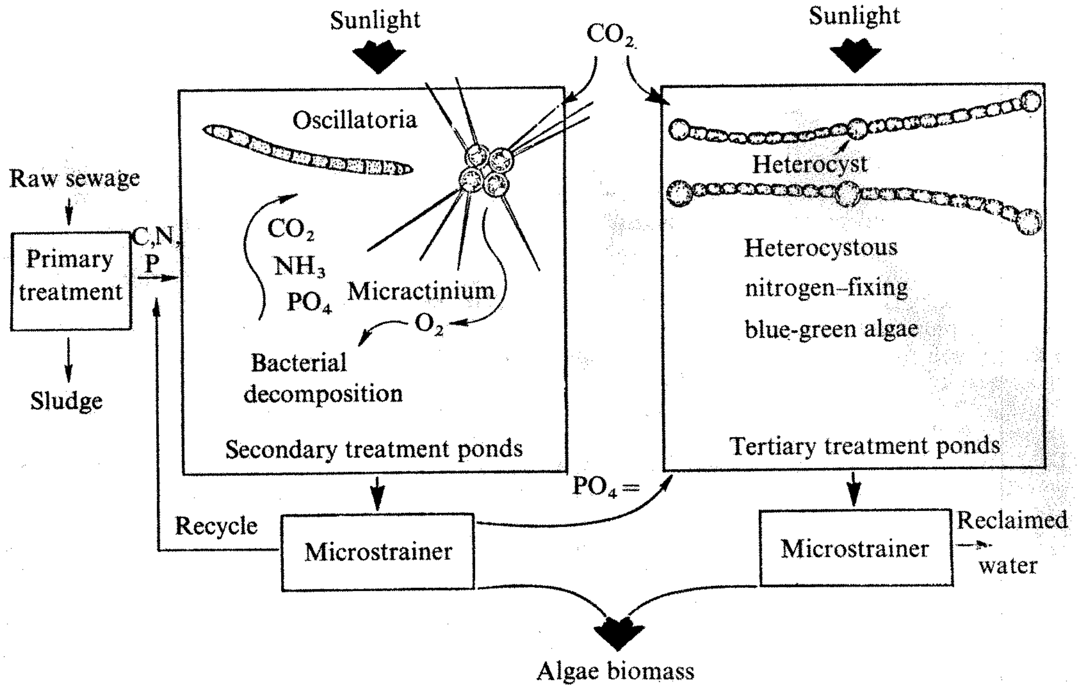

Fig. 2 Two-stage algal ponds for complete liquid waste treatment.

Algal species control

How, then, can algal populations be controlled so as to maintain selected algal species (or algal types) for prolonged periods? Sunlight and temperature cannot be significantly controlled, although they are critical to the succession of algal species. Pond loadings, depth, and mixing can be controlled, however; their particular effects on algal species are not yet known and would be influenced by additional environmental conditions. Thus, the selective species control methods must be adjustable in the face of changing conditions. Two such methods are presently being studied at our laboratory—size-selective recycle, and nutrient limitations.

The following is an example of size-selective recycle. In a pond operated at a five-day detention time, the predominant alga *Chlorella* is accompanied by a small percentage of *Micractinium*. *Chlorella* is the preferred food of many zooplankton such as *Daphnia*, whereas *Micractinium* is seldom grazed because its spines, which protrude in all directions (Fig. 2), obstruct ingestion by rotifers and similar zooplankton. The zooplankton cannot flourish because their population growth cannot keep up with the short detention time. If a relatively coarse screen were used to remove the *Daphnia* from the pond effluent and recycle it into the pond, a population explosion of *Daphnia* would be predicted to cause a diminished *Chlorella* population and thus lead to predominance of the undigestable *Micractinium*. Such biological control of algal species has yet to be demonstrated in ponds.

A more direct method of size-selective recycle has been used in outdoor ponds to achieve algal species control.[18] It involved recycling to the pond a certain fraction of the algae harvested by a microstrainer. If a pond is heavily inoculated with harvestable species and all the algae strained from the pond are re-introduced into the pond, these algae, because they are not washed out of the pond, will have an advantage over faster-growing but non-harvestable algae. Eventually, most of the algae in the pond will be of the desired, harvestable type and the amount recycled to the ponds can be decreased. To prevent non-harvestable algae from returning, the fraction of harvested algae that must be continuously recycled is proportional to the ratio of the relative growth rates. In practice, this recycling fraction must be larger since harvesting is neither completely selective nor totally effective. Thus, the growth rate of the desirable harvestable filamentous or colonial algal species must not be too far below that of the unwanted single-cell algae. The faster dilution rates or higher algal concentrations required by cell recycling also set limits to the allowable degree of recycling. It is important to note that such recycling is a size-specific, not a species-specific control method. Other strains of harvestable algae which spontaneously appear in the ponds will be recycled and become dominant if they grow faster than the inoculated strain. Inoculations and recycling might be alternated so as to allow true species control. The principles of selective biomass recycling are also applicable to any other harvesting method (such as settling) and to other large scale microbial processes including activated sludge, fermentations, and single-cell protein production. Indeed, in the activated sludge process, the practice of returning settled bacterial biomass to the reactor results in selection for settleable bacterial flocs.

The other method now under investigation for establishing harvestable species in ponds is based on nutritional limitation. The major nutrients of algae are water, sunlight, carbon, nitrogen, and phosphorus. The degree to which any one of these nutrients is limited will affect algal populations. To maximise biomass production, sunlight should be the only limiting nutrient, since productivity is proportional to solar energy conversion efficiency. However, the final yield of algae will be determined by the limiting nutrient in the wastes, which for domestic sewage is carbon. Treatment of sewage and other liquid wastes cannot be considered complete until nutrients causing eutrophication in receiving waters (N or P) are removed from sewage treatment plant effluents, and that means adding an additional source of carbon to algal ponds. Carbon dioxide produced by a power plant or any other source could easily be brought to ponds for this purpose and would allow growth of the harvestable algae (maintained through selective recycle) up to the nitrogen algal growth potential of the sewage. An additional crop of algae could be obtained from the residual phosphate in the effluents of these ponds through further carbonation. In such a final algal production and phosphate stripping pond, only nitrogen-fixing algae could grow (Fig. 2). Nitrogen-fixing algae are blue-green and all planktonic forms are filamentous. Thus, they are easily harvested and, since growth is selective, no recycling would be required.

Wherever phosphate detergents are used, nitrogen-fixing blue-green algal biomass can be produced in large quantities (exceeding the production of the initial ponds), thereby increasing the potential N fertiliser output from the ponds to a level above that present in the wastes.

Algal bioconversion

In the multi-pond system of waste treatment and algal biomass production proposed above and indicated in Fig. 2, two ponds in series (in practice several more would be required) are used to grow successive crops of different algal types harvestable by microstrainers or similar inexpensive methods. In such ponds, energy and plant nutrients are recovered from wastes and augmented by the processes of carbon dioxide enrichment and nitrogen fixation. The most direct and practical method for conversion of the algal biomass would be methane fermentation. Direct burning is not feasible since it would require dewatering of algae, a process requiring more energy than the algae could yield.

More than one-half of the heat of combustion of the algae (10,000 BTUs per lb algae) can be converted into methane gas with digester loadings, temperatures, and detention times similar to those of sewage sludge[20,21]. Many problems remain, including the possible resistance to degradation by part of the algal biomass, ammonia build-up in fermenters, and dewatering properties of the residual sludge. Of particular concern is the cost of conventional sludge digesters; covered anaerobic ponds might prove to be the most cost-effective large scale digestion systems. The production costs of methane would be part of the overall sewage treatment costs, making it a valuable by-product of algae-based waste treatment systems. The residues from algal digestion would contain virtually all the nitrogen and phosphorus of the algal biomass. These could be disposed of as fertiliser on agricultural land. In principle, all necessary agricultural fertiliser could be produced in this way—one acre of algal ponds providing the fertiliser required by 10 to 50 acres of modern agriculture.

The total amount of methane that can be obtained from the algal biomass produced during sewage treatment is limited to only a few percent of local natural gas needs. It has been demonstrated in laboratory studies that algae can be cultivated on the residues from algal methane fermentations.[22] Therefore, by recycling the fermentation residues to the algal growth ponds algal biomass production can be expanded to the limits of available water and land. However, in such cases, no waste treatment or fertiliser production credits would help underwrite the economics of methane production. In principle, capital investments (into pond construction) and operational costs (including energy inputs) could be low enough to allow large scale algal biomass production and conversion systems. The feasibility of such large scale 'nutrient integrated' systems will depend on the solution of many technical and economic problems.

Algal productivity

So far we have emphasised the problem of algal harvesting, species control, and bioconversion because they must be solved before large scale microalgal biomass production can become feasible. However, it is the harvestable yields of algal biomass (expressed as gm per m^2 per day or MT per hectare per year) that determines the potential of algal systems for energy and fuel production. There is no strong theoretical basis for expecting higher yields with algae than with higher plants. Vertical shade adaptation of leaves in a crop plant is inherently a more efficient arrangement than the uniform pigmentation of algae in a mixed water column. The reflectance of sunlight from the water surface is another disadvantage of algal ponds. However, algal ponds have several compensating features, primarily the capacity for continuously supplying all nutrients so that only light is limiting. Thus continuous culture makes possible a quick, graded response to environmental conditions and complete light absorption. The hydraulic nature of a pond system allows for simple and inexpensive operations. However, continuous cultivation also means harvesting of a dilute suspension of the microalgae. This is inherently more expensive than the periodic harvesting possible with macroalgae or land plants.

On the basis of even such a qualitative analysis, it may be concluded that rates of algal biomass production would not be necessarily higher than those observed in intensive agriculture, algal production, however, being potentially less demanding on inputs and efforts. It is not possible at present to make comparisons—many reported peak agricultural productivities are suspect on a number of accounts (methodology, border effects, and so on), and algal productivity is normally based on extrapolations from short term, small scale experiments. A figure of 50 MT per ha per yr (12 gm m^{-2} d^{-1}) of dry-weight, ash-free algal production has been presented as a reasonable figure of potential productivities[19]. This would represent a total solar energy conversion efficiency of about 2% at 30° latitude. It might be possible to perfect algal pond systems with higher conversion efficiencies. This will require careful pond operations and genetic selection of the algal strains to be cultivated. For example, the addition of carbon dioxide to ponds could be used (in addition to the reasons listed above) to maintain an adequate *p*H in the ponds (it may go above 10 in the afternoons, resulting in a sharp decline of photosynthesis). This would not only extend the daily growing period, but also reduce photorespiration and the potential for photooxidative death[23]. Another factor which could increase photosynthetic efficiencies and which may account for some of the very high yields reported is the phenomenon of photoheterotrophy. Many algae assimilate preformed organic compounds, particularly under low light intensities (as may be expected in the bottom of ponds). Since little light energy is required in the photoheterotrophic production of biomass, calculated efficiencies are high because the energy content of the liquid wastes are ignored. Controlled photoheterotrophic growth would increase the performance (load rates, organic waste destruction, and biomass production) of the primary ponds receiving settled sewage. Photosynthetic bacteria are, of course, photoheterotrophic by nature and are potentially useful in waste treatment systems. Another suggestion for improving photosynthetic efficiencies would be through decreasing the accessory pigment concentration of the algae to decrease self-shading and photoinhibition.

An important aspect to be considered is the reduction in net photosynthetic efficiencies resulting from energy inputs into pond operations such as dilution, mixing, fertilisation, harvesting and concentrating, species control, and so on. If the large scale production of algae for energy production is to be feasible, these inputs must be minimal. A slight net energy gain has been calculated from waste-grown algae using available production methods[24]. In principle, net algal productivity should not be limited by the energy requirements of cultivation which are low; mixing at slow speeds (about 5 cm s^{-1}) is sufficient for thermal destratification and requires little energy[25,26]. Harvesting by microstrainers is likewise not energy intensive. Water usage in pond systems is mainly through evaporation; the ability of microalgae to grow in brackish or saline waters would make it possible to use unreclaimable water exhaustively through use of a terminal evaporative pond system. Fertilisation obviously would be too expensive if mineral or synthetic fertilisers are used; nutrient recycling, whether from wastes or internally, is required. Nitrogen fixation must make up extra nitrogen requirements at a probable reduction in photosynthetic efficiencies estimated at 10%. Including energy inputs and conversion losses, a net production of 200 M BTUs per acre per year of methane seems to be a feasible goal[19,27].

Future developments

The use of microbial photosynthesis for energy production is not limited to methane and fertilisers. Biophotolysis—the decomposition of water to yield hydrogen gas—has been demonstrated with algae in the laboratory[28,29]. Heterocystous blue-green algae can be used to produce hydrogen and oxygen simultaneously in a system of horizontal glass tubes[30]. Other algae might be capable of alternating daytime oxygen with night-time hydrogen production. Photosynthetic bacteria can produce hydrogen from organic substrates[31], presenting a potential alternative to methane fermentation[32]. The production of specialised chemicals is possible. The large scale culture, of the salt-loving alga, *Dunaliella,* consisting of 80% glycerol, has been proposed (M. Aaron personal communication). Algal species containing high concentrations of fats and lipids may be used for liquid fuel production. Petrochemical feedstocks of various types may theoretically be derived from algae. However, such technologies are probably going to take longer to perfect.

Microalgal bioconversion will have a beneficial impact on environment and society as long as it does not conflict with food production or develop into gigantic centralised conversion systems. The prospects of very large scale sites (hundreds or thousands of square miles) converted to pond systems is not imminent; technological development will certainly at first favour smaller locally integrated waste treatment-algal biconversion-nutrient recycling systems. These would be of particular value where adequate insolation is combined with a need for sanitary sewage disposal and fertiliser supplies. Such pond systems may expand, as practicable, to dispose of salt-laden agricultural drainage water by evaporation and to provide a significant fraction of local fuel needs. Energy production from microalgae might have little immediate overall impact on energy consumption of advanced industrial countries, except where favourable local situations exist. Algal bioconversion is specifically important to underdeveloped countries since such technology would require little or no investments in scarce raw materials or complex 'hardware'. The application of sophisticated cultivation technology should be within the reach of even the poorest countries. The environmental and social impacts of algal pond systems or other bioconversion technology are expected to be minor compared with present or alternative energy sources. In the future, the developing technology of bioconversion can present mankind an alternative to depleting fossil fuels and dangerous reliance on nuclear energy.

Lateral mobility of human erythrocyte integral membrane proteins

Velia Fowler & Daniel Branton

The Biological Laboratories, Harvard University, Cambridge, Massachusetts 01238

Fluorescein isothiocyanate-labelled integral membrane proteins are mobile in the membranes of human erythrocytes that have been fused (and haemolysed) by Sendai virus or polyethylene glycol. Minimum diffusion coefficients are of the order of 10^{-11} *cm*^{2} *s*$^{-1}$ *at 37 °C. This mobility is reduced several-fold at room temperature, not detected at 0 °C, and is significantly greater in fresh than in aged blood. Mobility was assessed by observing the spread of fluorescence on labelled cells which had been fused with unlabelled cells; neither intramembrane particle aggregation nor spectrin release occurred during this process.*

FACTORS which regulate the lateral mobility of cell surface components have been described for a number of cells[1,2], but the complexity of these cells makes it difficult to study the relevant interactions at the biochemical level. The erythrocyte membrane is more readily accessible to direct biochemical investigation but it is generally thought that lateral movements of proteins in this membrane either do not occur or are extremely limited[3,4]. Antigenic components, visualised using direct and indirect immunofluorescent staining[4,5] and fluorescein-conjugated lectins[6], have not been observed to patch or cap in membranes of adult erythrocytes from various species. Similarly, the intramembrane particles exposed by freeze-fracturing are not readily aggregated in the intact erythrocyte[7,8]. These particles represent proteins intercalated into the lipid bilayer[9,10],

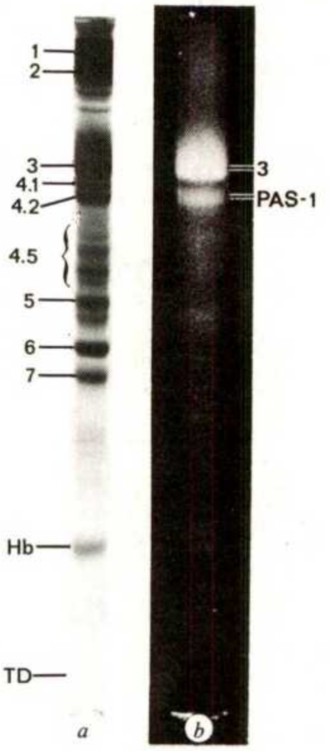

Fig. 1 A 7.5% SDS–acrylamide gel of fluorescein isothiocyanate-labelled erythrocyte membranes. *a*, Proteins stained with Coomassie brilliant blue. *b*, The same gel before Coomassie blue staining, showing fluorescent labelling. Intact erythrocytes were labelled by a modification of the method of Peters *et al.*[15]. Outdated human blood stored in acid–citrate–dextrose (about 3–6 weeks) was washed twice in 310 mOsm phosphate-buffered saline, *p*H 7.6 (PBS), removing the buffy coat after each wash, and then twice in 145 mM NaCl–10 mM $NaHCO_3$, *p*H 9.5. The packed cells were resuspended in an equal volume of a 5 mg ml^{-1} suspension of an FITC–cellite adsorbate (Sigma) in the same buffer, and agitated overnight at 4 °C. The cells were resuspended in 50 mM glycine–95 mM NaCl–10 mM $NaHCO_3$, *p*H 9.5, to stop the reaction, and layered over a $\rho = 1.13$ metrizamide shelf (32% diluted to 23.8% in the NaCl–bicarbonate buffer). After centrifugation the cells were collected from the interface, the celite having sedimented to the bottom of the tube. The cells were washed once again in the glycine–bicarbonate buffer, then twice in PBS. Ghosts were made according to Dodge *et al.*[25], omitting the saline and isotonic phosphate buffer steps. Gels were run according to Fairbanks *et al.*[26]. The fluorescent gels were photographed while still in the tubes, using a long wavelength ultraviolet lamp for excitation, and a yellow barrier filter with Tri-X film. The negative was scanned with a Joyce–Loebel densitometer, and comparison of the areas under the peaks revealed that greater than 70% of the total label was present in the Band 3/PAS-1 region (> 50% in band 3). No fluorescent material ran in front of the tracker dye (TD), and less than 10% of the label migrated immediately behind the tracker dye, where both free FITC and some lipids migrate in this gel system. The fluorescent band just below Band 3 on these 7.5% acrylamide gels could be readily identified as PAS-1 by its altered mobility on 5% gels[27].

and have been attributed to the principal erythrocyte integral membrane proteins, Band 3, and the major sialoglycoprotein[10–14]. Peters *et al.*[15], labelled a heterogeneous group of components in the human red cell membrane (both proteins and lipids were labelled) with fluorescein isothiocyanate, and measured the rate of fluorescence recovery after bleaching one half of the erythrocyte ghost. They observed essentially no recovery of the bleached half in the conditions of the experiment, implying that the labelled components, if diffusing at all were diffusing only very slowly in the plane of the membrane.

But, prostaglandin-induced changes in erythrocyte membrane lipid fluidity detected using electron spin resonance techniques[16,17], paralleled by changes in membrane circular dichroism spectra[18] and in the rheological properties of the blood cells[16,18], indicate that both lipid fluidity and protein–protein associations may play a dynamic part in the cell's response to its environment. Two recent reports indicate that surface antigens of intact human red cells can indeed undergo redistribution in the plane of the membrane. Clustering of fluorescein-labelled anti-blood group A antibodies has been correlated with a change in erythrocyte morphology from a biconcave disk to a crenated sphere[20], and a temperature dependent redistribution of concanavalin A (con A) bound to the cell surface, induced by anti-con A antibodies, was visualised directly on the erythrocyte surface by freeze-etching[21]. Here we report results which demonstrate a time and temperature dependent mobility of labelled proteins in the plane of the adult human erythrocyte membrane. The basic strategy of these experiments was suggested by Frye and Edidin's initial demonstration of antigen intermixing in mouse–human heterokaryons[22].

Membrane labelling and cell fusion

Membrane proteins which have been operationally defined as integral[23,24] were labelled with fluorescein isothiocyanate (FITC) (Fig. 1). After fusion (and haemolysis) of labelled and unlabelled cells with Sendai virus or polyethylene glycol (Fig. 2), the proportion of fused cells which was uniformly fluorescent increased with time except at 0 °C (Fig. 3); this is due to spreading of label over the surface of the initially bright-dark cells. Although only the end points were scored, all degrees of fluorescence distributions from bright on one half and dim on the other, to a barely distinguishable difference between the two halves, were observed.

Redistribution of label was not due to movement of fluorescently labelled haemoglobin or other cytoplasmic components because when fused lysed cells were washed in 20 mOsm phosphate buffer, *p*H 7.6, resuspended in 310 mOsm phosphate-buffered saline, *p*H 7.6, and then incubated at 30 °C (fluorescent haemoglobin was only about 1% of the total labelled protein in such ghosts) label redistribution proceeded as in unwashed cells. (This procedure was not used routinely because hypotonic lysis and subsequent resuspension in isotonic buffer resulted in shrinkage and crumpling of the membranes, making it difficult to positively identify the fused cells.) Furthermore, treatments which

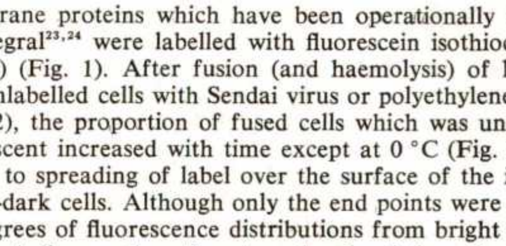

Fig. 2 An FITC-labelled cell fused with an unlabelled cell, incubated for 2 h at 22 °C. Haemolysis accompanied fusion. *a*, Fluorescence photograph. *b*, Phase contrast photograph of the same cell. ×1,280. Cells were fused by Sendai virus as follows. A 50/50 mixture of a 5% (v/v) suspension of labelled and unlabelled cells in PBS was added to an equal volume of PBS containing between 5,000 and 10,000 HA per ml of egg-grown Sendai virus. This was shaken at 150 r.p.m. at 0 °C for 15–20 min to agglutinate the cells, and then at 37 °C for 10–12 min. The fusion step was terminated either by addition of an equal volume of ice-cold 310-mosM PBS while vortexing rigorously to break up agglutinates, or by washing the cells once in about 10–15 volumes cold PBS (SS-34, 10,000 r.p.m., 30 min, 4 °C) with subsequent resuspension in an appropriate volume of PBS. As a control in some experiments, cells were fused with a 50% polyethylene glycol (molecular weight 6,000) solution by a modification of the procedure of Davidson and Gerald[28] for fusion of cultured cells in suspension. Fused cells which survived this process behaved as cells fused by Sendai virus.

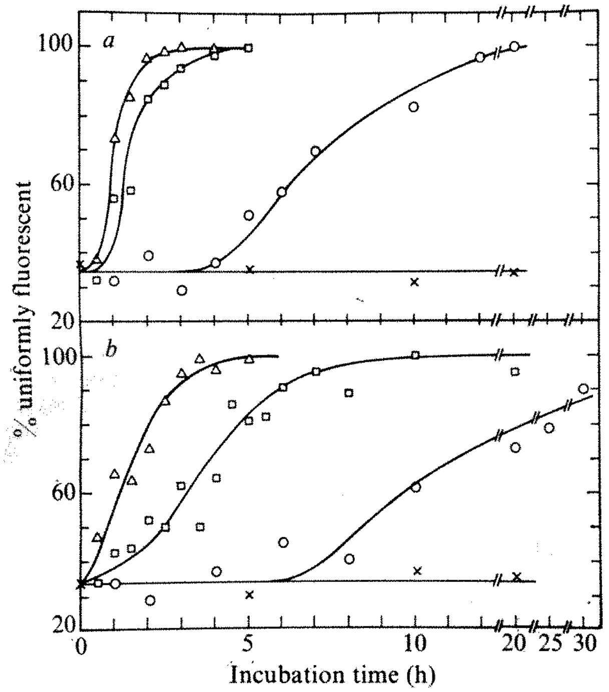

Fig. 3 Redistribution of label on FITC-labelled cells fused with unlabelled cells. Uniformly fluorescent fused cells expressed as % of the total number of fused cells which are at least partially fluorescent. *a*, Fresh blood. *b*, Aged blood stored 3–6 weeks in acid–citrate–dextrose at 4 °C. △, 37 °C; □, 30 °C; ○, 23 °C; ×, 0 °C. Note the breaks in the time scale at long incubation times. Cells were fused by Sendai virus as described in Fig. 2. After fusion, the cell suspensions were divided into four portions, incubated at the indicated temperatures, samples taken at various times and kept on ice until counted. To prevent bacterial growth, 0.5 mM NaN_3 was routinely included during the incubations; curves for redistribution of label were identical in the presence and absence of azide. Fused fluorescent cells were scored as uniformly fluorescent, that is, no difference in intensity was distinguishable on one half of the fused cell relative to the other half, or as not uniformly fluorescent, that is, some difference was visible. A total of 100 cells from each sample were scored for the determination of each point; points from one representative experiment are plotted. Note that at 0 time one third of all fluorescent fused cells are uniformly fluorescent; these result from the fusion of two initially fluorescent cells with one another. This is the expected outcome of a fusion process in which it is equally likely for any cell to fuse with any other and in which only fluorescent fused cells are counted.

remove the so-called 'peripheral' proteins[23,24], such as low ionic strength extraction, high salt washes, *p*-chloromercuribenzoic acid, or 10% acetic acid treatments[24,29], failed to elute any fluorescence from ghosts or fused cells. Spreading of label is also not due to movement of dye molecules which have simply adsorbed on to or partitioned into the membrane, since less than 10% of the total fluorescent label migrates in the position of free fluorescein isothiocyanate on sodium dodecylsulphate (SDS)–acrylamide gels (Fig. 1). In addition, FITC–celite pre-incubated in 50 mM glycine–95 mM NaCl–10 mM $NaHCO_3$, *p*H 9.5, did not label the cells, and all cells were washed in this buffer after labelling (Fig. 1).

Fusion was always accompanied by haemolysis. But, neither proteolysis nor extensive intramembrane particle aggregation could be detected in Sendai virus-treated erythrocytes. SDS–acrylamide gels of haemolysed and fused cells incubated at 37 °C until label had become uniformly distributed were identical to gels of ghosts from untreated cells (Fig. 1) in terms of fluorescent labelling and staining with Coomassie blue. SDS–gel electrophoresis is sufficiently sensitive to detect proteolysis of ghost membrane proteins by microgram per millilitre quantities of trypsin[30,31]. Moreover, proteolysis leads to vesiculation of the ghosts[30] and clustering of the intramembrane particles[14], which were not observed after treatment by Sendai virus. Samples of the supernatant and the pellet of cells fused and incubated in the same buffer without resuspension were electrophoresed in parallel. Supernatants to which was added an amount of spectrin (bands 1 and 2) and actin (band 5) corresponding to less than 10% being released from the cells into the lysate provided a standard for comparison, and demonstrated that the treatments used in our experiments did not result in detectable spectrin (or actin) release from the membrane. It was important to rule this out, since the ability to induce redistribution of the intramembrane particles has been correlated with previous treatments which dissociate the peripheral membrane proteins spectrin (and actin) from the cytoplasmic surface of the membrane[8]. In addition, curves plotted for label redistribution in polyethylene glycol-fused cells (not shown) correspond closely to those for Sendai virus-fused cells (Fig. 3).

Membrane protein mobility

The abrupt increase in uniformly fluorescent haemolysed and fused cells after a short lag time is particularly striking at physiological temperatures. Decreasing the temperature to 22 °C dramatically slows the rate of label redistribution, and further reduction of temperature to 0 °C prevents it completely. It is evident from the curves obtained that some fused lysed cells become uniformly fluorescent sooner than others. This heterogeneity is most clearly visible at lower temperatures where the rates of label movement are slower. Evaluation of variations in the rate of label movement at physiological temperatures is difficult, due to the errors involved in determining rates by scoring a population of fused lysed cells for each time point. Direct determination of rates on individual fused cells by measuring the increase in fluorescence intensity on the initially dark half of the fused cell would clarify this question.

Approximate diffusion coefficients for minimum rates of label redistribution have been calculated (Table 1). Using fresh blood, Peters *et al.*[15] set an upper limit on the diffusion coefficient for fluorescein isothiocyanate-labelled components in the erythrocyte ghost membrane at 3×10^{-12} cm^2 s^{-1} at 22 °C, which compares favourably with our value of 6×10^{-12} cm^2 s^{-1}. The diffusion coefficients which we calculate at 37 °C are about an order of magnitude greater, however, and approach those determined for plasma membrane proteins in other cell systems, which fall between about 10^{-11} and 10^{-10} cm^2 s^{-1} (refs 33–38). The possibility that the fusion and lysis process itself affects the lateral

Table 1 Minimum diffusion constants determined for FITC-labelled integral membrane proteins in the erythrocyte

Temperature (° C)	Fresh blood (cm^2 s^{-1})	Aged blood (cm^2 s^{-1})
37	4×10^{-11}	2×10^{-11}
30	3×10^{-11}	1×10^{-11}
23	6×10^{-12}	2×10^{-12}
0	No movement of label observed	

Approximate diffusion coefficients for the integral proteins of the slowest cells to show complete label redistribution were determined from the data in Fig. 3. The formula developed by Huang[32] for diffusion from one half of a spherical shell into the other was used, assuming first that the time course of label redistribution on these cells can be approximated by such an exponential decay process, and second that the fused cell doublet was a sphere with a surface area twice that of a single cell (verified by measurement on photographs of fused cells). We further assumed that the time for label equilibration on the slowest cells was the time at which at least 90% of the initially bright–dark fused cells had become uniformly flourescent, and that such fused cells would appear uniformly fluorescent to the human eye when twice the relaxation time for label equilibration in a fused doublet had elapsed (compare Fig. 2 in ref. 32).

mobility of the labelled proteins cannot be ignored. It is significant, however, that the diffusion coefficient inferred for membrane antigens at 37 °C in mouse–human heterokaryons produced by fusion with Sendai virus[22,23,32] is within the range of values we have found in fused red cells. A pronounced dependence on relatively small variations in absolute temperature seems to be characteristic of the lateral mobility of membrane proteins[22,39], in contrast to the far more rapid diffusion of membrane lipids, which is relatively unaffected by corresponding variations in temperature[33–38]. Factors such as membrane viscosity, phase transitions and separations of the membrane lipids, boundary lipids associated with a particular protein, and dynamic interactions with other proteins, within or beneath the bilayer[2], almost certainly regulate the lateral mobility of these membrane proteins.

Table 2 Effect of an ATP regenerating system on the rate of redistribution of label

Time of incubation (min)	% Fluorescent fused cells uniformly fluorescent			
	Fresh blood		Aged blood	
	+ATP	−ATP	+ATP	−ATP
0	36	36	32	32
30	40	36	—	—
60	75	52	44	32

Freshly drawn blood was washed thoroughly and aged to reduce intracellular ATP levels by incubation at 37 °C for 16 h in 135 mM NaCl, 20 mM $NaHCO_3$, 3 mM KCl, 2 mM $MgCl_2$, 1 mM $CaCl_2$, and 200 μg ml^{-1} benzylpenicillin, *p*H 7.6 (ref. 41), and then labelled as for Fig. 1, simultaneously with freshly drawn blood from the same donor. Cells were fused with Sendai virus as for Fig. 2, the suspensions were divided into two portions and washed once in 310 mOsm PBS, *p*H 7.6, as described in Fig. 2, and then resuspended in either PBS (−ATP), or PBS plus 1 mM ATP, 2 mM $MgCl_2$, 5 mM phosphoenolpyruvate, 20 μg ml^{-1} myokinase, 50 μg ml^{-1} pyruvate kinase, *p*H 7.6, (+ATP), and incubated at 37 °C as described in Fig. 3. The omission of either phosphoenolpyruvate or ATP from the regenerating system gave results which were not significantly different from those in PBS alone.

The marked differences in rates of label equilibration for fused lysed cells made from fresh blood as compared with aged, ATP-depleted[40] blood suggested that intracellular ATP levels might affect the lateral mobility of the membrane proteins. Incubation of the fused lysed cells in the presence of an ATP regenerating system increased the rates of label redistribution significantly (Table 2). Since cells from both aged and fresh blood are invariably haemolysed during fusion and are thus equally depleted of metabolites, and since the presence of an ATP regenerating system does not decrease the length of time for label equilibration to equivalent values for both fresh and aged cells, factors in addition to energy availability probably control the lateral mobility of these membrane proteins. Cell shape, deformability, and divalent cation content change dramatically during cell ageing and ATP depletion[40,41], and may have an important role in these complex phenomena.

Discussion

Observations of parameters influencing the lateral distribution of the intramembrane particles exposed by freeze-fracture have led to the notion that lateral movements of the integral membrane proteins are restricted by a spectrin–actin meshwork beneath the erythrocyte membrane, either by a direct linkage mechanism or by trapping between the interstices of the meshwork[8,24,42]. As pointed out before[8], however, aggregatability of the intramembrane particles must be distinguished from direct measurements of protein mobility. The importance of distinguishing between particle aggregation and mobility becomes evident if it is borne in mind that treatments which induce particle aggregation perturb the membrane. Such perturbations may alter dynamic interactions between proteins so as to favour associations that restrict mobility.

Moreover, although the intramembrane particles seem to consist, at least in part, of Band 3 and the principal sialoglycoprotein [10–14], they may not coincide with the fluorescently labelled proteins whose mobilities we observe at a light microscopic level. Our data do not exclude the possibility that some of the proteins in the erythrocyte membrane are less free to diffuse than others, since the rates of label movement which we observe represent an average, both over a population of cells and a population of integral membrane proteins. But, if all the label present in the Band 3 region (at least 50%, see Fig. 1) were to be immobilised with respect to the other labelled components, we would expect that at the end point, the population of fluorescent fused cells would consist of approximately 33% uniformly and brightly fluorescent cells and 66% in which three-quarters of the label is on one half of the fused cell and one-quarter on the other half. This is not the case. A report that the rotational diffusion of Band 3 proteins (labelled with eosin isothiocyanate) is not affected by removal of most of the spectrin from erythrocyte ghosts[43] is additional evidence that protein mobility and particle aggregation are controlled by different factors. Specific and dynamic interactions between spectrin[44], or other peripheral membrane proteins, and the integral membrane proteins may regulate the lateral mobilities and associations among proteins in the plane of the membrane. This could provide a potential mechanism for the dynamic interaction between extracellular events and internal metabolic processses in the erythrocyte.

Plate linkage mechanism to account for oroclinal deformation in the Western Cordillera of North America

W. B. Heptonstall

Grant Institute of Geology, University of Edinburgh, West Mains Road, Edinburgh, UK

Plate tectonic theory is used to predict the motion of small plates which remain coupled within discrete regions to adjacent large plates. Taking the Western Cordillera of North America as an example, it is shown that the three oroclines situated between Vancouver and Northern California are very largely removed when that portion of the orogenic belt south of the Klamath mountains is rotated back in time with the Pacific plate while retaining the northern Cordillera as a rigid portion of the American plate. The rotation at the Pacific–America pole is found to be 14.4° which suggests that the deformation began during the Oligocene.

PLATE boundaries are generally well defined, both seismically and topographically. When traced out around the globe they are seen, in most cases, to divide the surface into a number of discrete plates each decoupled from its neighbours. There are, however, regions where the boundaries cannot easily be delineated, for example, in parts of the Mediterranean or the southerly continuation of the East African Rift. There may be various reasons for the uncertainty including, in some instances, a lack of seismicity. There is also the possibility, however, that some of these regions are more complicated than is implied by a simple plate tectonic interpretation. Wilson[2] envisaged plate boundaries to be of three types which are currently referred to as spreading ridges, subduction zones and transform faults. Thus a ridge may change or be 'transformed' into a fault or subduction zone at what he called a transform. To these three we may add a fourth type of boundary where the plates become attached to one another. Clearly this situation can only exist very briefly because of the rapid build-up of stresses induced by the relative motion between the plates. Such a situation must have existed in Baja California when this portion of the North American plate was transferred to the Pacific[3]. Here the outcome was relatively straightforward and with new transform faults and intervening ridge segments developing to the east of Baja to accommodate the strain. In other similar instances an alternative process may sometimes have occurred whereby the two original plates remain joined by a sliver of lithosphere which is hinged to each. Consider for example, the plate shown in Fig. 1*a* which is being split apart by rifting. If instead of a single fracture, there develop two major fracture zones, neither of which is able to completely truncate the plate. Motion of the northern half in a north easterly direction pulls the sliver away from both the northern and southern plates. Assuming the sliver to remain rigid except in the vicinity of the hinging points, then finite motion cannot occur until a third hinge pole labelled γ in Fig. 1*b* becomes established somewhere between the other two. For any defined finite rotation between the two major plates, there must exist a unique solution to the orientation of the small 'linked' plates.

Over 20 years ago S. W. Carey noticed that, while some orogenic belts are dominantly linear in plan view, others show sharp inflections[4]. The question which he posed then and which remains today is whether such bends were part of the orogenic belt at the time it was forming or whether they formed later hence representing what he called 'an impressed strain'. He assumed the latter interpretation to be correct and defined the term orocline for such bends. We may see how the concept of hinging small plates to large ones can explain the formation of oroclines by considering a hypothetical linear orogenic belt labelled ABCD in Fig. 2*a*.

The northern portion A is kept fixed and the southern portion D is allowed to move with resepect to A. The pole AD is placed at various points on the stereogram and in each case the rotation angle of D to A is 20°. To accommodate this rotation without rupturing the orogen, two link plates are permitted to form, namely B and C. The kinks which subsequently appear, due to the rotations, are shown in Fig. 2, *b*–*f*. The poles AB and AD are fixed with respect to the stereogram while BC and CD are instantaneous. The latter two poles may, however, be located since the distances between the hinge poles are known. Poles AC and BD are instantaneous with respect to the stereogram and to all four plates. They may be located by graphical means using the

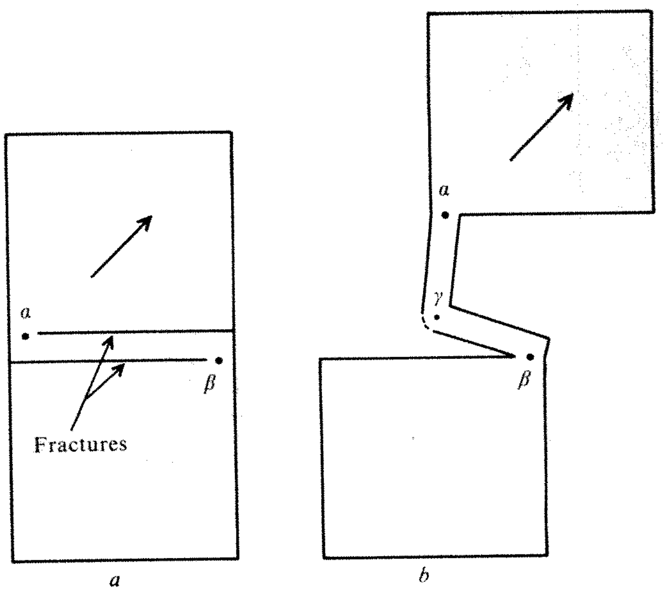

Fig. 1 One of several ways in which linked plates may form. *a*, The northern portion of the plate begins to pull away towards the north east causing fractures. These fractures do not sever the plate but instead leave the fractured central portion joined at α and β. *b*, With finite motion the distance α to β decreases causing the interconnecting plate to buckle at a third point γ.

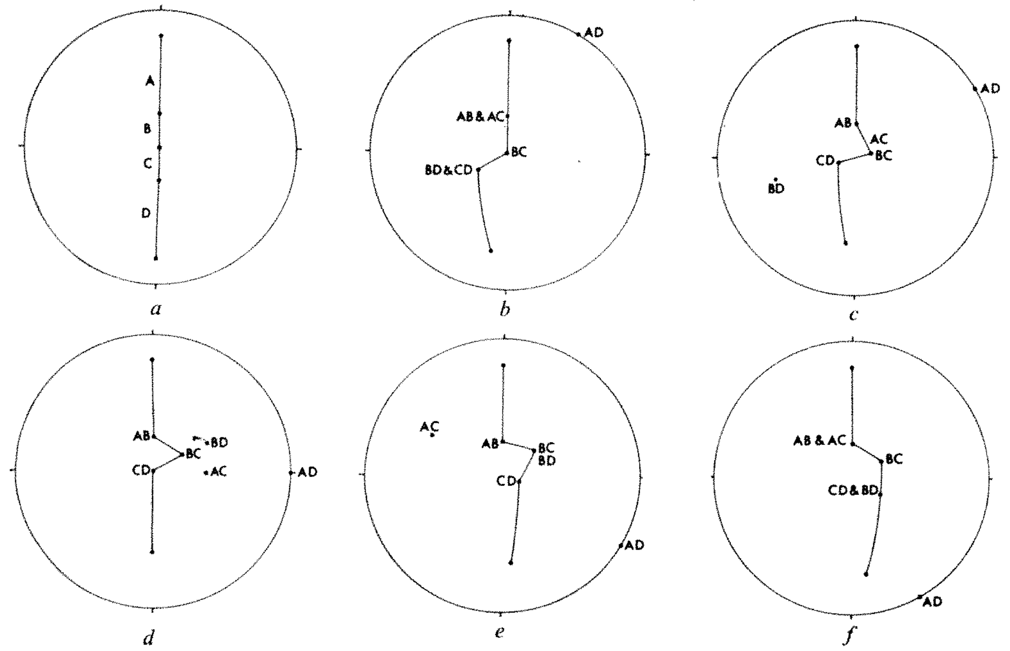

Fig. 2 Diagram illustrating how different oroclinal configurations may develop depending on where the pole of relative motion for the driving plates is located. *a*, Initial condition with linear orogenic belt ABCD. *b–f*, Oroclines generated by placing the pole AD at five different points on the great circle which forms the equator of the Lambert equal area projection.

property that the three poles for any triple plate problem always lie on a great circle. Thus considering, for example, the pole BD in Fig. 2; this occurs at the intersection of the two great circles passing through first CD and BC and also that through AB and AD. Not only are the locations of poles BC, CD, AC and BD instantaneous, but for a given constant rate of pole AD, rates at all the other poles vary continuously.

Carey realised that oroclines do not usually occur in isolation and grouped them together in pairs[5]. In doing so, he recognised left lateral and right lateral shear as the cause and defined the structures as being sinistral and dextral coupled oroclines respectively. In applying the plate tectonic interpretation outlined above, we see that it is impossible for rigid plates to rotate about two hinge poles and it follows that either the lithosphere is not behaving rigidly in these conditions or else the oroclines should occur in sets of three. Where three oroclines are present, the terms dextral and sinistral are inappropriate, however, it is apparent that the deformation shown in Fig. 2 could have proceeded in such a way that the hinge pole BC moved out of line towards the west rather than to the east.

The Cordillera along the western margin of North America show several sharp inflections in the trend of both the orogenic belt and the outcrop pattern of the associated granitic intrusions. These bends have been interpreted as being due to dextral shear by several authors including Carey (refs 5–7). The evidence in support of these bends being secondary is from palaeomagnetism and from various branches of geology. Palaeomagnetic results from the Siletz River volcanics in Oregon[8] and the Columbia Plateau basalts[9] all show a clockwise rotation subsequent to their formation. The geological evidence includes the trend of the structural grain of the rocks which is seen to follow the outcrops of the orogenic belt and is hence deflected through large angles at the oroclines. Other evidence comes from the turbidites of the Tyee formation in Western Oregon which in their present configuration, are seen to have flowed northwards into an oceanic embayment in the continental margin rather than to the west into the Pacific[10].

An examination of the geological map of North America shows the orogenic belt to be dominantly linear between latitudes 60°N and 52°N. Near Vancouver Island however, there is a sharp bend which deflects the belt along with the granite plutons through approximately 30° and this is taken to be the third orocline which, along with those identified by Carey[5], is required in order that these bends may have developed by linkage of rigid plates. Further south the orogen is seen to bend in Idaho from a NW to SE trend between Vancouver and Idaho to almost NE to SW betwen Idaho and the Klamath Mountains. South of the Klamath Mountains the belt apparently runs in a SSE direction parallel to the Sierra Nevada; however the late Tertiary volcanic rocks in the Cascade Mountains and the sediments in the Great Valley may conceal the fact that relative motion has occurred between these two regions during or after the period of oroclinal deformation.

If the bends are accepted as oroclines then the driving mechanism can only have come from the relative motion between the Pacific and American plates. It is envisaged that a small portion of the latter became rigidly attached to the Pacific plate in mid Tertiary times when that segment of the Farallon plate between the Pioneer and Murray fracture zones was completely consumed in the subduction zone[3]. The process was probably essentially similar to the incorporation of Baja California into the Pacific plate but in this instance the relative motion did not enable this piece of the Cordillera to become completely sheared off from America. Instead, the compression was transmitted all the way up the orogenic belt as far as, or even past, Vancouver and it was forced to buckle at the three weakest points. Once these kinks or hinge poles became established, then it should have been possible for the deformation to proceed in such a fashion that the segments of the Cordillera in between remained rigid. The edges of these segments should then have followed the rules of plate tectonics from which we may predict the nature and amount of compression and/or extension between them and the American plate.

In accordance with Carey's practice of giving names to the oroclines, I shall refer to the hinge poles in order from north to south as Vancouver, Idaho and Klamath respectively. Unlike other poles of relative motion which are merely the geometrical consequences of the motion of rigid plates, hinge poles have considerable geological significance since they represent the sites of profound tectonic activity. The linked plates in between these poles will be referred to as the Washington plate north of the Idaho hinge pole and the Oregon plate between the Idaho and Klamath poles.

To restore the orogen to its original shape, the required parameters are the coordinates of the three poles and the coordinates and rotation angle of the pole of finite relative

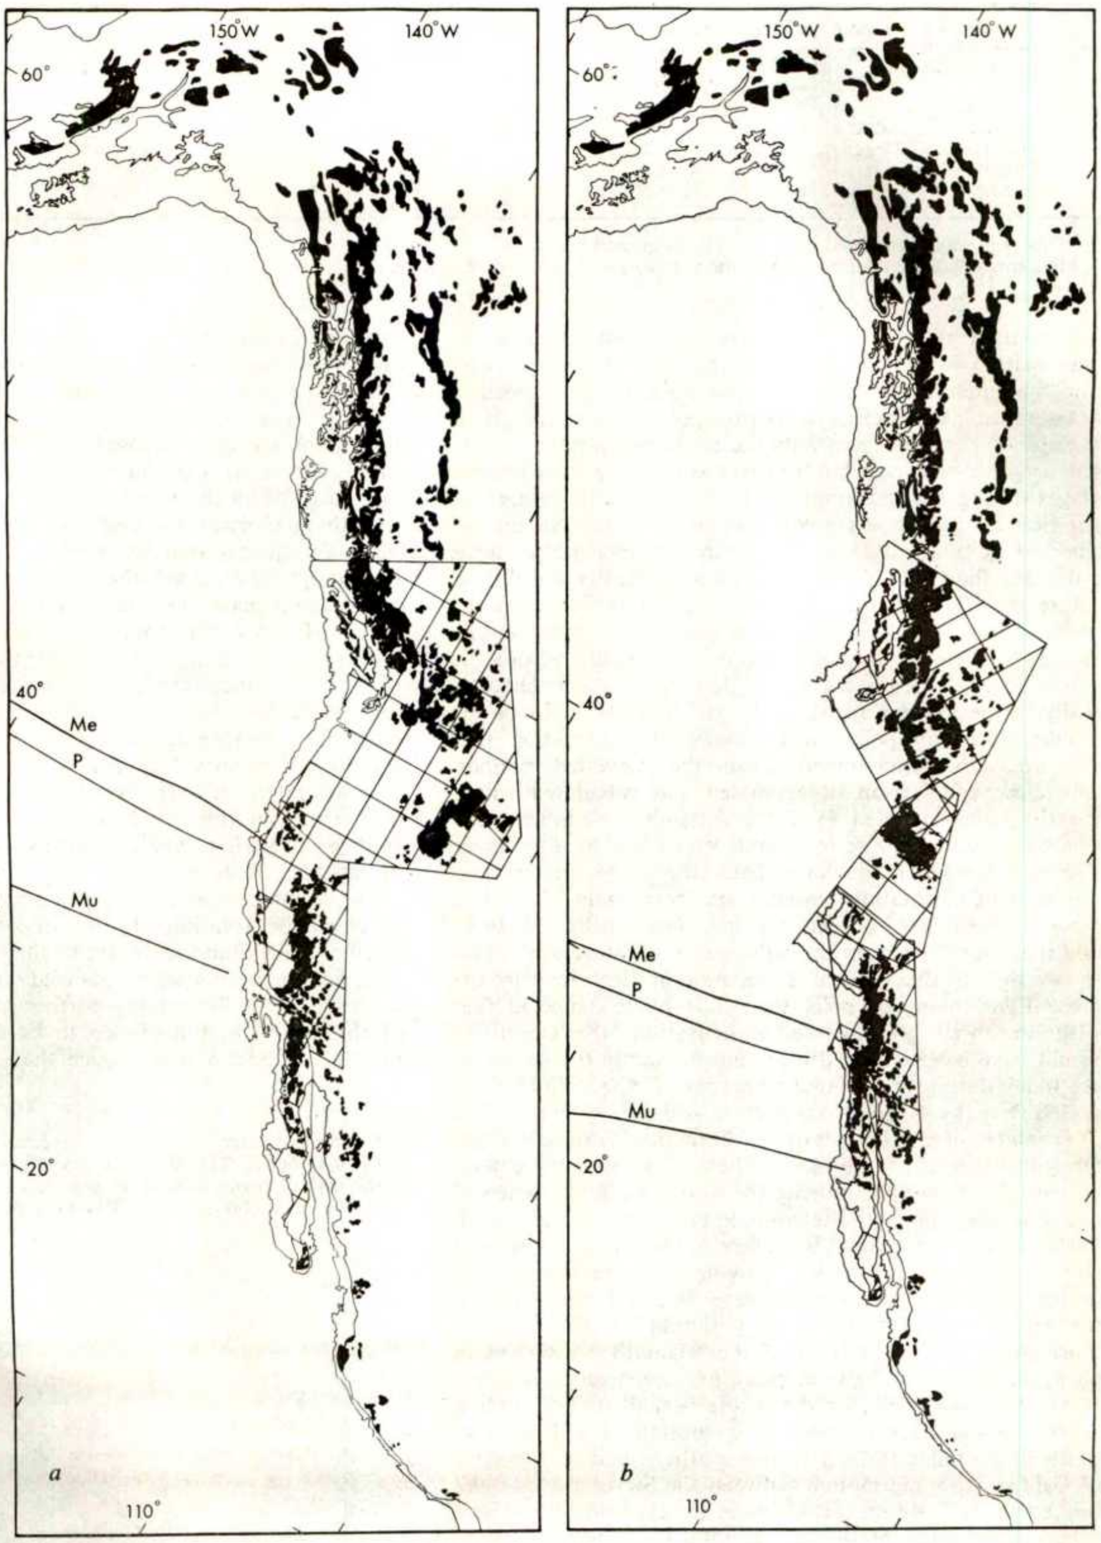

Fig. 3 The western margin of North America showing: *a*, the present configuration of the proposed linked plates and *b*, the Mid Tertiary (approximately 30 Myr ago) orientation of these plates as predicted by the model described in the text. Areas shaded in black are Mesozoic granitic intrusions. Fracture zones on the Pacific plate are Me, Mendocino; P, Pioneer and Mu, Murray.

motion between the Pacific and American plates for the period in question. The locations of the poles between the linked plates have been estimated from the tectonic map of North America[11] and are listed in Table 1. The youngest magnetic anomalies between the Pioneer and Murray fracture zones vary from 10 in the north to 6 in the south[3]. This suggests an age of between 32 and 26 Myr BP as the time of onset of oroclinal deformation while the opening of the Gulf of California 4 Myr ago[12] may be taken as marking the end of that deformation. The pole and angle for the finite motion during this period cannot be determined directly and indirect methods using circuits involving perhaps five or more plates lack precision[13]. For these reasons, I shall use the best available data for the instantaneous relative motion[14]. Even more uncertain than the location of the pole is the rotation angle for the period. Molnar and Atwater have shown, using plate circuits, that the instantaneous rate was significantly slower in mid Tertiary times than at present and their reconstruction for 29 Myr ago suggests that a rotation of about 14° has occurred between then and the beginning of the opening of the Gulf of California. Instead of using this angle, we may proceed to determine the rotation required to line up the three hinge poles on a great circle, this being the maximum possible angle as further rotation would require the orogenic belt to have been longer before the oroclinal

Table 1 Estimated rotations taken from maps compared with predicted values using the proposed plate tectonic model

Plate pair	Pole		Rotation angle (°)	
	Lat.	Long.	Estimated	Predicted
America–Washington	51.0°N	127.0°W	30	31.4
Washington–Oregon	45.5°N	115.0°W	110	114.0
Oregon–Pacific	42.0°N	123.5°W	80	70.8
Pacific–America	52.0°N	76.0°W*	14†	14.4

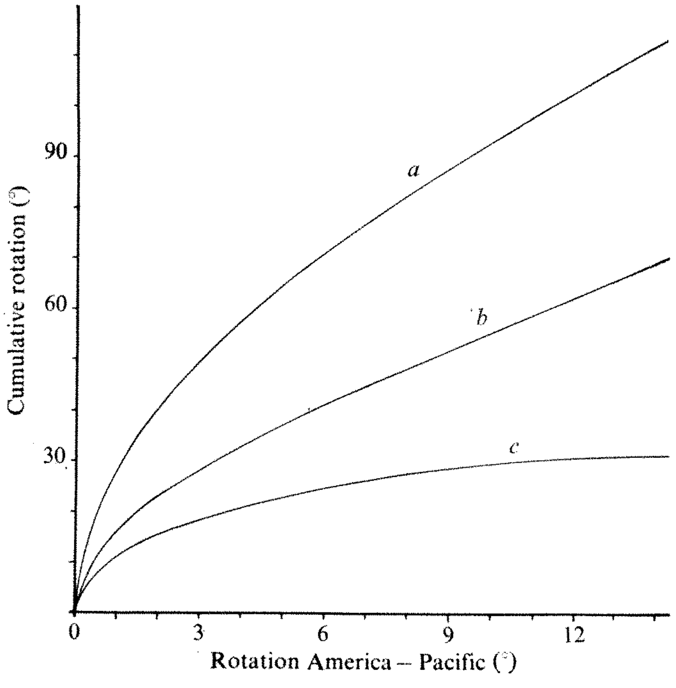
*This pole was determined by Chase and is quoted in ref. 14.
†This angle has been determined by the writer using Chase's pole and the 29 Myr b.p. reconstruction in ref. 13.

deformation than it is at present. A computer program was written to determine the locations of the hinge poles and the amount of rotation at these poles for any specified rotation at the Pacific–American pole. Using this it is possible to determine not only the angle required to line up the orogenic segments but also to examine the intermediate stages during the deformation. It was found that 14.4° of rotation about Chase's pole[14] was required to line up the three hinge poles; the rotations which are incurred at these poles are shown in Table 1. It is geometrically possible to rotate the Klamath pole about any arbitrary point on the globe to line up the three hinge poles on a great circle. However, such rotation would not, in general, restore the whole orogenic belt to a great circle configuration. Theoretically, there exists a great circle which is the locus of the Pacific–American pole which satisfies the condition that the orogen be straightened out in the suggested manner. The close comparison of estimated and calculated values for the rotation listed in Table 1 tends to confirm that Chase's pole lies on, or is at least very close to, this locus. The distance along the locus from the orogen determines the amount of rotation required and here again, there is a close resemblance between the calculated value of 14.4° and that estimated from the published reconstruction[13]. This shows that if the pole of finite motion lies close to the present instantaneous pole, then it is to be expected that with an initial great circle configuration, the Cordillera would have been distorted into almost exactly the shape we see today during the allotted time span of about 25 Myr.

Before making the reconstruction which is shown in Fig. 3, estimates of the boundaries of both the Washington and Oregon plates had to be made. These must, to some extent, be tentative, however, moving them to a limited extent will not seriously modify the tectonic implications of the model. Perhaps the most critical boundary is the one between that part of California which was moving with the Pacific, and its contact with the American plate. It is not obvious from the geology where this boundary should be placed but it must have been to the east of the Klamath Mountains in northern California. It is unlikely to have been to the east of the Sierra Nevada for the whole period of deformation as this would have opened up a substantial gulf further south in a similar fashion to the southern end of the Gulf of California. Some motion between the Sierra Nevada and the Basin and Range province is here assumed to have occurred, however, as this can account for the late Tertiary dilation and consequent faulting in this region. By analogy with the present San Andreas transform fault, it is likely that the boundary in question was also a fault and this may now be largely concealed by the sediments of the Great Valley. The most likely location, however, seems to be in the metamorphic belt of palaeozoic and mesozoic strata on the north-western flanks of the Sierra Nevada batholith. Here faults with a suspected strike slip component[15] may be traced over 300 km from the Cascade Mountains in the north to the eastern margin of the Great Valley where presumably they continue under the late Tertiary sediments.

We may now examine the nature of the relative motion between the linked plates and the American plate in greater detail by dividing up the total rotation at the Pacific–American pole into 24 increments of 0.6°. In doing so, each increment represents approximately 1 Myr. The cumulative rotations at the hinge poles are shown in Fig. 4 while in Fig. 5, lines joining these poles at every third increment are superimposed on a simplified geological map of the area. It can be seen that the rates of rotation decreased at all three poles with time from which it follows that the geological processes associated with these rotations must also have varied accordingly. If we take, for example, the compression along the Rocky Mountains between the Washington plate and the American plate, it is found that about 90% of the total compression was accomplished during the first half of the period. From the migration path of the instantaneous pole between the Oregon and American plates (see Fig. 5) it is predicted that initially there would have been compression along the entire boundary between the two. The early compressive phase at the southern end may at present be represented on the American plate by the belt of metamorphic rocks to the west of the Sierra Nevada referred to earlier. The outcrops show a bend of about 25° at latitude 37°N which if due to oroclinal deformation could be interpreted as being caused by the initial high rate of clockwise rotation of the Oregon plate relative to the Pacific. With time the nature of the motion on the Oregon–American plate boundary changed with extension beginning in the south and migrating northwards. During the last half of the period it is predicted to be dominantly extensional throughout and it is envisaged that at this time the Sierra

Fig. 4 Cumulative rotations at the three hinge poles as predicted by the model. The slope at any point on these curves gives the instantaneous rate in relation to the American–Pacific rate. Curve *a*, Idaho pole; *b*, Klamath pole; *c*, Vancouver pole.



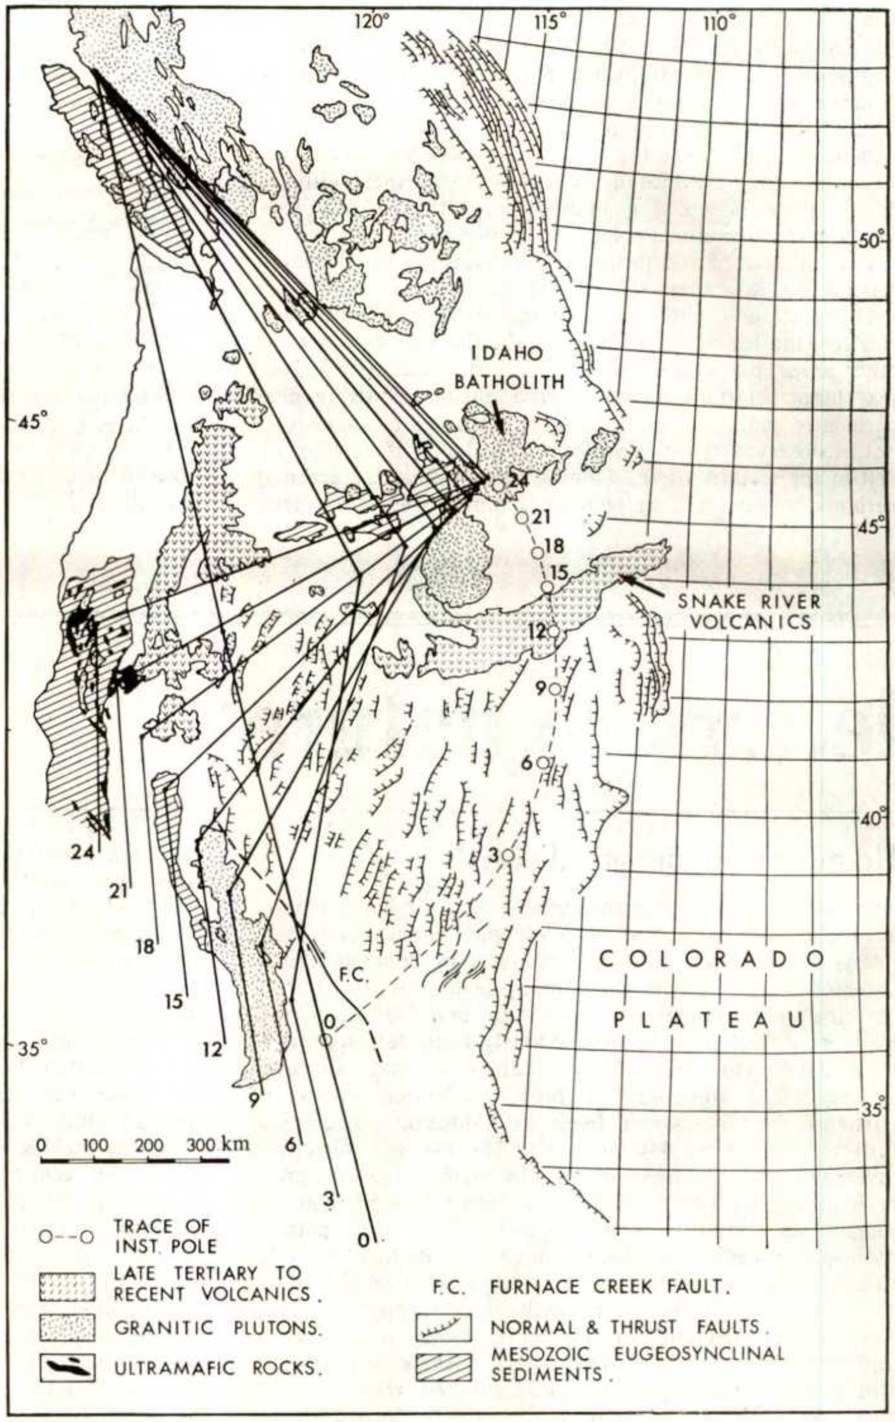


Fig. 5 Simplified geological map of the region showing the predicted motions of the linked plates and hinge poles in relation to the American plate. For clarity only a third of the 24 increments which were used to construct Fig. 4 are shown and each therefore represents a rotation of 1.8° between the American and Pacific plates. The trace of the instantaneous pole across the Basin and Range province is that for the motion between the Oregon and American plates.

Nevada region moved with the Pacific plate. In doing so, it would have moved north-westwards relative to the Basin and Range and it is likely that most of the motion was taken up on the Furnace Creek fault. Tension was generated in two distinct areas at this time namely, the Great Basin (north of latitude 36°N) and the Southern Basin and Range (between latitudes 36° and 28°N). In the former case, the relative motion was controlled by the Oregon–American pole and there is some indication that the normal faulting in this region has a radial distribution about a point in central Idaho (see Fig. 5). The implied degree of extension is very large, particularly on the western side of the Great Basin, from which I conclude that, in addition to the visible faulting, some of the dilation must be hidden under the vast areas of late Tertiary volcanism. In particular, the rifting and volcanism in the vicinity of the Snake River may be attributed to the final phases of deformation. Here instead of the extension being distributed over a broad zone as it is elsewhere, it became very much more localised. This may simply be due to this region being so close to the pole of relative motion. If the Snake River downwarp was initiated at the time that the instantaneous pole was crossing it, then we should expect the volcanism to appear first in the west where the extension rate was highest. The time of this initial rifting would have been about 15 Myr before the present according to the model which compares favourably with a radiometric age of 13 Myr for the oldest Snake River rocks[16]. As the pole migrated further north, so the more easterly portions of the rift would have opened up and hence we can account for the observed age progression from west to east with time[16]. The other region undergoing extension at this time lay to the south of the Sierra Nevada. Assuming the Sierra Nevada to have moved with the Pacific place for say half of the total rotation, then the extension between this and the American plate would have amounted to about 400 km. The Southern Basin and Range may be traced in a NW–SE direction over a distance of about 1,200 km so here again considerable dilation is predicted. If there is sufficient evidence to show that this is too high then we may be led to assume that the motion of the Sierra Nevada with the Pacific plate occupied a smaller proportion of the total rotation between the Pacific and American plates.

The validity of the proposed mechanism will ultimately depend on how well it can explain all the large scale Tertiary tectonic phenomena in the Western Cordillera of North America. The mechanism should also be tested in other areas, particularly where palaeomagnetic data suggest that large rotations have occurred during relatively brief periods of geological time. In some instances oroclines may not be observed as they require the existence of an orogenic belt in the vicinity of the hinging poles. While linkage may perhaps be favoured in tectonic regimes where the crust has a strong grain, there does not seem to be any reason why it should not also be found to occur elsewhere.

I thank Drs J. E. Dixon, A. G. Smith and D. Wright for making available a copy of Dr R. L. Parker's program SUPERMAP; I also thank G. Yarwood for the extensive modifications which he has made to this program.

letters to nature

Uranus rings: an optical search

The discovery of rings surrounding Uranus[1-4] has prompted a careful re-examination of telescopic observations made nearly a year ago with a new type of solid-state area detector called a charge-coupled device or CCD. The extreme narrowness of the individual Uranus rings explains why they had not previously been detected either by visual or conventional photographic methods, for even if they were composed of highly reflecting, ice-coated particles, the rings would likely be hidden in the glare of reflected light from Uranus itself. The average reflectivity (averaged over the disk) of Uranus in the blue and green regions of the spectrum is very high, ~ 0.55–0.60. At longer wavelengths, however, methane in the planet's atmosphere begins to absorb much of the incident solar radiation, hence the bluish-green appearance of Uranus in the telescope. In the deep methane absorption band at 886 nm the reflectivity of the planet drops to only 0.012, and Uranus would thus appear very dark to any detector which was sensitive to this near-infrared region of the spectrum. It is of particular significance to the ring detection problem that such imaging would suppress the light reflected from the planet relative to that reflected from any nearby solid bodies, such as satellites or ring particles, by a factor of nearly 50. Unfortunately, most detectors have lost nearly all of their detectability at wavelengths longer than 800 nm.

The CCD is an exception. Low noise and quantum efficiencies of 0.5 and higher permit telescopic imaging of Uranus in the 886 nm methane band with acceptably short exposure times. In May 1976 we obtained several dozen images of Uranus in this band using a CCD camera at the f/13 cassegrain focus of the University of Arizona's 154 cm (Mt Lemmon) telescope. Exposure times ranged between 1 and 5 min. These images, recorded digitally on magnetic tape, have recently been re-examined to see if they contain any hint of the Uranus rings. Because the widths of the individual rings[1] lie way below the resolving power of any groundbased telescope, we can evaluate only an average reflectivity based on the simplifying assumption that all of the ring material is spread uniformly between the innermost and outermost rings—a region of space extending from 44,000 to 51,000 km from the centre of Uranus. Evidence of the rings has not been found in any of the CCD images. But it is possible to set an upper limit of approximately 0.0001 for the average reflectivity as defined above.

A preliminary examination of the reported occultation events implies that these narrow rings occupy ~2% of the space between the innermost and outermost events, and an analysis by Hubbard indicates that the individual rings themselves are only partially (approximately one-half) filled with solid particles[5]. If these numbers are accepted as being essentially correct, we find that the average reflectivity of the individual particles must be at most a few per cent, much closer to that of carbonaceous chondritic material than to the ice-coated particles in the rings surrounding Saturn[6-8]. Considering the extremely low temperatures characteristic of this remote part of the solar system (<90 K), this preliminary conclusion on the nature of the Uranus ring particles comes as somewhat of a surprise.

This work was supported in part by NASA (grant NGL 03-002-002) and JPL (contract 954057). I thank F. Landauer of JPL for the availability of the CCD camera; J. Janesik and L. Hoveland of JPL and S. Larson and J. Fountain of LPL for observing assistance.

Observations of Uranus occultation events

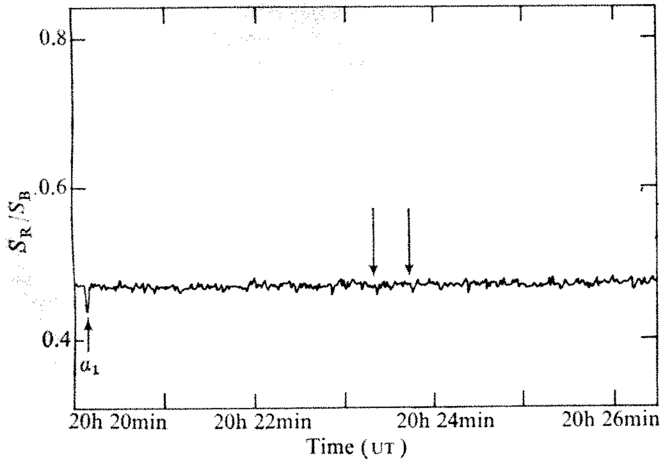
A PRELIMINARY analysis of photometric data obtained by Zellner at the Perth Observatory during the Uranus appulse to SAO 158687 on 10 March 1977 shows at least three brief occultation events which appear to coincide with portions of a Uranian ring system reported by Elliot *et al.*[1]. No occultation by Uranus itself occurred at Perth. Our group also obtained an observation by Smith with a portable telescope from the vicinity of Mauritius. The data are marginal due to variable transparency but it seems clear that there was no occultation by Uranus which diminished the stellar intensity by more than 50%. No ring events were observed from Mauritius due to the onset of a rain shower. Our observations at Perth, along with the null result from Mauritius, can be combined with other available data[2–5] to improve the deduction of the geometry of the ring features, and to obtain a preliminary upper limit to the radius of Uranus.

Our Uranus photometers recorded photon counts at 10 ms intervals on a red and a blue channel simultaneously. The red channel used an RCA C31034 photomultiplier at an effective wavelength of 8,000 Å, while the blue channel accepted light shortward of 5,000 Å, using an uncooled EMI 9789-B tube. The blue channel was used as a monitor of sky transparency and Uranian scintillation and could be used to help reject spurious 'occultation events'. In addition, both channels were chopped to the sky at a nominal frequency of 50 Hz in order to give independent measurements of sky background for point-by-point subtraction. An uncoated pellicle mirror permitted simultaneous guiding. The photon counts were recorded using a portable cassette tape recorder.

Observations at Perth, which enjoyed favourable weather, were made with the 41-cm telescope of the Western Australian University at the Perth Observatory. According to plan, data recording commenced at 20:20 UT, and shortly afterwards an occultation event of almost exactly 1s duration occurred (Fig. 1). This event was not observed by the adjacent experiment of Millis *et al.* on the 61-cm telescope which was being recentred at the time; possible subsequent low-amplitude events at 20:23:19 and 20:23:43 reported by the latter[3] are not apparent above the noise in our data, even at 0.1 s time resolution. At 21:04 UT, our observer switched to a new cassette, during which data recording was interrupted for 20 s. Observations then continued until approaching dawn terminated operations at 21:45 UT. Just before this point, two more 1 s duration occultations were observed (Fig. 2). Quite accidentally, because of different observing procedures, none of the three major events observed by Millis *et al.* were also observed by Zellner, or vice versa.

The absolute timing of our data records is established by a time signal placed at the beginning of the first cassette and at the end of the second. Final determination of the times of the occultation events is nearly complete; the preliminary times[4] already leave little doubt that the three events correspond, in the notation of Elliot *et al.*[1], to a crossing of the α-ring on the immersion side (α_1), a subsequent recrossing of the α-ring on the emersion side (α_2), followed by a crossing of the β-ring (β_2).

Fig. 1 Initial observation of the α-ring at Perth. Data have been averaged to 1 s time resolution, and the ratio of the signal in the red channel to that in the blue channel is plotted. The stellar base line is approximately at $S_R/S_B = 0.34$. Because of the narrowness of the α feature, at this time resolution the full drop is somewhat washed out. The location of putative events at 20:23:19 and 20:23:43 is indicated.



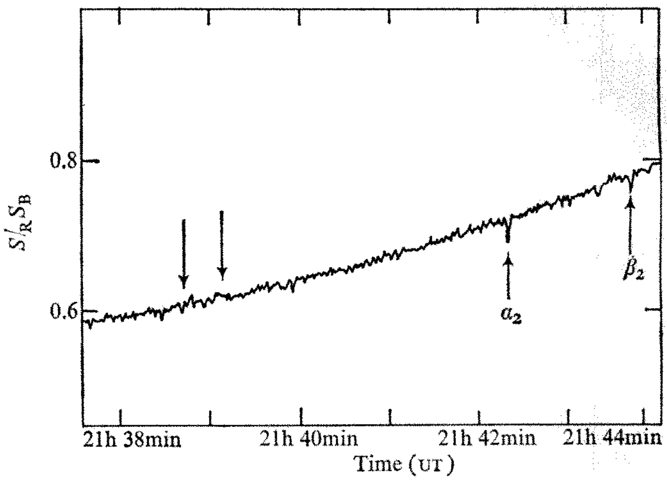


Fig. 2 Subsequent observation of the α-ring and the β-ring on the east side of Uranus. Increasing redness of the sky is caused by the approach of dawn. Possible location of rings interior to α, if they continue around the planet, is also shown.

Inspection of the data at high time resolution shows that the maximum loss of light during the α-occultations is about 50% of the steller intensity. The β-event is considerably weaker and is only marginally detected against the rapidly brightening sky. We find that the general characteristics of the α-occultations can be reproduced by a model with a randomly-placed array of occulting bodies with dimensions on the order of 1 km or smaller and an areal density ~ 50% over a band of about 10 km width. For a point source, such an array would produce intense scintillation due to diffraction. Such scintillation is not observed, nor is it expected in view of the angular size of the occulted star. Photometry by Wisniewski indicates that SAO 158687 is probably a K3III star with a projected diameter at Uranus of approximately 4.5 km, and this value has been used in the model.

We have made a preliminary fit to all timings available to us (Fig. 3), under the assumption that the rings are circular features lying in the adopted orbital plane of Uranus' satellites[6]. For each of the five confirmed rings, the coordinates of the centre of the orbit and the radius were adjusted to the best least-squares fit. We have already concluded that neither the inner four rings (α, β, γ, δ) nor the outer ring ε are truly concentric circles to within their widths. Consider two concentric circles which are crossed by an arbitrary straight line. Clearly the two line segments contained between the circles are of equal length, and will remain equal if the circles are tilted and projected to form ellipses. The relative times α–β at Perth for immersion and emersion do not satisfy this theorem, nor do many of the other relative times which are available. Small corrections for nonlinearity due to the earth's rotation etc., do not change this conclusion. Although the four inner rings are not quite concentric, and therefore time-variable, the best fits to their centres coincide to within about 100 km, and indicate a further correction[5] to the Uranus ephemeris (relative to the star) of 0.15 arc s south and 0.015 arc s west. Using the ε ring alone, the

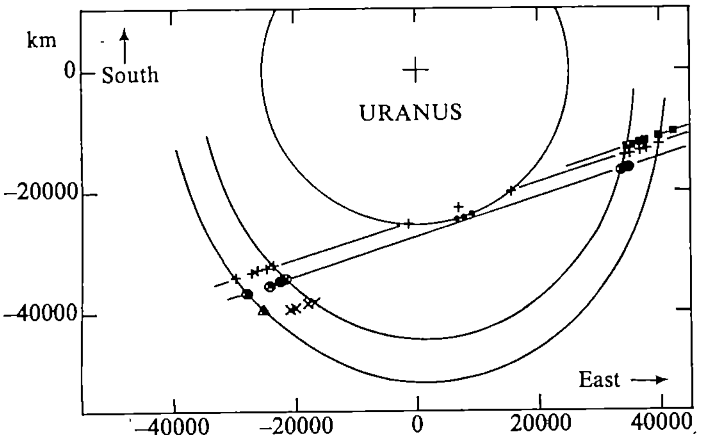

Fig. 3 Uranus occultation events. + observations of Elliot *et al.*[1–3]; ■ observations of Churms[3]; ○ observations from Perth[3,4]; ● observations from Mauritius; △ observations by Bhattacharyya and Kuppuswamy[3,4]; × observations by Mahra and Gupta.

indicated southward correction is 0.05 arc s and the westward correction is 0.015 arc s.

The degree of consistency between the ring centres can be used to locate the centre of mass of Uranus to within the same accuracy. This assumption is only valid to the extent that the limited sample of the rings from the occultation chords is not systematically affected by local ring distortions. If this is so, we then conclude that the null result at Mauritius together with the inner ring solutions places an upper limit to the radius of Uranus of 26,300 km, in opposition to a value of 27,900±500 km proposed earlier by Smith[7]. A radius as small as 25,100 km would be consistent with the ε-ring solution. We may be able to determine the radius more accurately by using the atmospheric occultations (Elliot *et al.*[1] and Churms[3]), if there is also an occultation of a few per cent in the stellar intensity at Mauritius. This effect will be sought if we can successfully correct for the effects of clouds to this accuracy.

Our group has also attempted observations from the 91-cm telescope at Hartbeespoort, South Africa, and from the 102-cm telescope at Sutherland, South Africa. We also participated in a joint experiment with the University of Cape Town on the Sutherland 188-cm telescope. None of these experiments obtained data because of heavy cloud cover at both sites.

This work was supported by NASA grants NSG-7045, NSG-7238, and the National Geographic Society. We gratefully acknowledge our host observatories at Perth, Hartbeespoort, and Sutherland, and the technical assistance of I. Nikoloff. We thank the governments of Australia, Mauritius, and South Africa for valuable support.

Wave optics of the central spot in planetary occultations

THE detection of a bright central spot[1] during the occultation of ε Geminorum by Mars[2] has demonstrated that an exponential planetary atmosphere can act as a lens with somewhat peculiar properties. In the course of a general study of certain wave-optical phenomena in planetary occultations, we have carried out an investigation into the diffraction nature of the central spot, which has not been previously considered in occultation theory. Some of the results are presented in this letter, along with implications for possible future experiments.

Assume that an observer is at a distance D from a spherical planet of radius R. The planet has a refracting, non-absorbing, exponentially stratified atmosphere with scale height H. Observations are made at wavelength λ. We assume that $(\lambda D)^{1/2} \ll H$, $\lambda \ll (HR)^{1/2} \ll D$, and $R^{3/2} \ll DH^{1/2}$. Then the planet can be regarded as a phase object[3] which modifies the phase of an incident plane wave from a distant point source by

$$\Phi_\lambda = \alpha\lambda^{-1}\exp(-r_1/H) \qquad (1)$$

where α is a constant and r_1 is the distance of closest approach of the optical path to the centre of the planet. The optical axis is then the straight line linking the centre of the planet and the distant source. Let the distance of the observer from this axis be r. Superimposing the partial waves, we calculate the intensity for $r \ll R$

$$I(r) = (2\pi)^2 \frac{RH}{D\lambda} J_0^2 \left(\frac{2\pi Rr}{D\lambda}\right) \qquad (2)$$

normalised such that the unocculted intensity $I(\infty) = 1$. The distribution of intensity resembles the Airy function and has a typical width

$$w \sim D\lambda/R \qquad (3)$$

For $w \ll r \ll R$, the average intensity goes over to the previously-derived[1,4] ray-optical result, $I \sim 2H/r$.

These results imply that, in principle, the central occultation spot could be observed to obtain very high resolution of distant objects. Assume $H = 10$ km, $D = 1$ AU, $\lambda = 5{,}000$ Å, and $R = 4{,}000$ km (Mars or Venus). The width of the central spot image of a point source is then $w \sim 2$ cm, corresponding to a theoretical resolving power of $\sim 10^{-13}$ radians (equivalent to 4 km at 1 pc). The light gathering power of the 'telescope' can be expressed in terms of an equivalent aperture R_e for a conventional telescope:

$$R_e^2 \sim I(0)\, w^2 \qquad (4)$$

We find $R_e \simeq 100$ m for this example.

Since central occultations by suitable planets are rarely seen from the Earth's surface, presumably use of the central spot technique would require the use of spacecraft to place the observer at the image of the source to be investigated. In principle, one could profitably use the technique to observe such objects as quasars, white dwarfs, and pulsars. However, certain grave practical difficulties must be mentioned:

(1) The point spread function of equation (2) is not as well-defined as the Airy function. The sharp central peak has broad wings which fall off as r^{-1}. Deconvolution of images of extended sources would thus be difficult, although objects such as binary point sources could probably be readily identified. (2) It would evidently be quite difficult to locate the image of a true point source because of its small size. (3) A real planet would be an imperfect lens. The optical axis is poorly defined for an oblate

planet, such as Mars[1]. This problem could be reduced by using a slowly rotating planet, such as Venus. Since the atmosphere will in general be turbulent, the instantaneous image may differ considerably from the ideal image shown by equation (2).

Video tape recording of a possible ball lightning event

PHOTOGRAPHS purporting to be of ball lightning have been published by a number of authors, as discussed for example by S. Singer[1]. More recently, what is believed to be the first photograph of the formation of ball lightning has also been presented[2,3].

For the past four years I have been associated with a lightning research programme in the Transvaal Highveld region of southern Africa, in the course of which various photographic techniques have been applied routinely to the study of several aspects of the lightning discharge. Incorporated among these techniques has been the use of an automatic video tape recording system using a television camera with a silicon diode array target tube, in a manner similar to that originally reported by Winn *et al.*[4]. Particular advantages of this system in comparison with conventional photography include an enhanced sensitivity and sufficient time resolution to resolve the majority of multiple-stroke flashes. Over the past two lightning seasons some 500 lightning strokes to ground have been recorded and studied using this system.

During a thunderstorm on the evening of the 12 November 1976, a video tape recording which included a ground flash exhibiting particularly unusual characteristics was obtained. The resultant video tape was played back field by field and the individual still pictures rephotographed on a conventional display monitor. The complete event, which lasted for approximately 180 ms, is shown in Fig. 1. (The nominal time resolution of the video recording system is the time taken to sweep one field, that is, 20 ms—hence the intervals indicated in Fig. 1.) Inherent in the operation of the silicon target array is the ability to retain images of very short duration luminous events. Therefore, each still photograph constitutes an 'integrated' record—sampled at 20 ms intervals—of what is in all probability a complex process, exhibiting several stages of transient re-illumination.

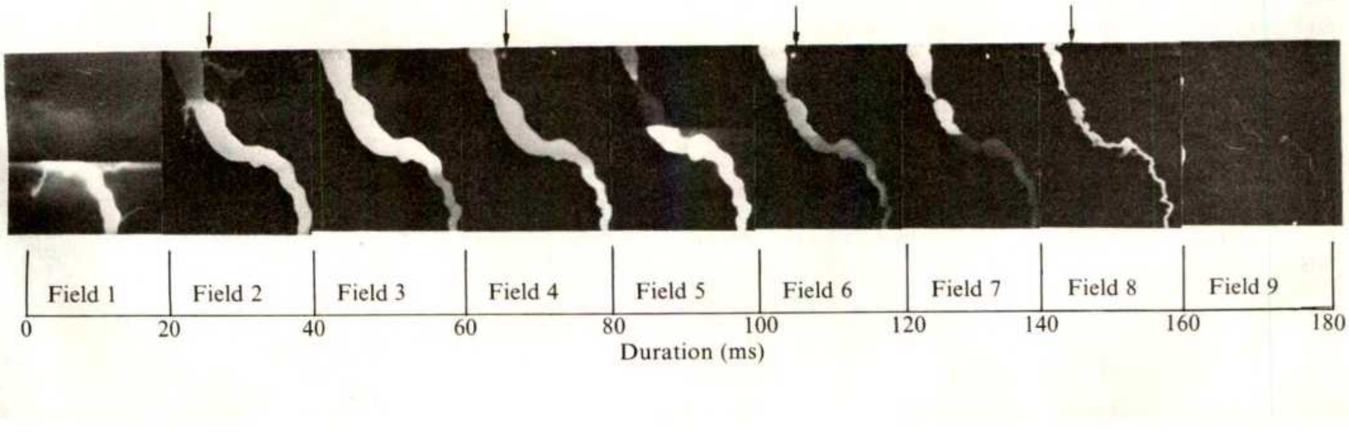
The first field in the sequence shows a faint image of a downward leader, together with the subsequent bright return stroke—which must have occurred at a time when about half the field had already been swept during the raster scan. (The 'blooming' of the very bright return stroke image is a feature of this type of camera—particularly for intense nearby strokes such as this flash, which occurred about 700 m from the camera—as determined from time-to-thunder measurements).

Thereafter, in the remaining fields of the sequence, a further three subsequent return strokes may tentatively be identified. (The main criterion for the identification of a return stroke is for a significant enhancement of channel luminosity to be apparent in relation to the images on preceding fields. Although the silicon diode camera has inherently low image persistence, remanent image persistence can occasionally make the identification of subsequent strokes rather difficult, especially in the event of short inter-stroke intervals).

Of particular interest in this sequence, however, is the recurrent appearance of a ball-shaped image in fields 2, 4, 6 and 8, apparently detached and to the right of the top portion of the main channel, except in field 2 where its position seems to coincide with that of a branch. It is interesting to observe (in Fig. 1) that the 'ball' re-illuminations seem to have occurred during the inter-stroke intervals, rather than at the times when the main discharge channel was re-illuminated by the passage of the bright return strokes. This would tend to discount the possibility of the ball being an artefact—arising as the consequence of a blemish on the lens, for example, or from a raindrop on the camera face. (No such blemish was recorded elsewhere on the video tape and no rain had occurred at the time when this flash was noted, nor for more than 10 min after the flash).

The final return stroke is followed by an indication of the persistence of a decreasing 'continuing current', as is known occasionally to occur[5] and as has frequently been recorded in the course of my measurements. However, the images of the channel in fields 8 and 9 are unusual in that they display an excessive tortuosity, together with what may be construed as 'beading'. The latter phenomenon is frequently reported to be associated with ball lightning events[1]

Fig. 1 Video-taped image sequence of multiple-stroke lightning flash showing possible appearance of ball lightning. Field 1, leader and first return stroke. Field 2, fading image of first return stroke; first appearance of ball-shaped image. Field 3, second return stroke. Field 4, fading image of second return stroke; second appearance of ball-shaped image. Field 5, third return stroke (during scan). Field 6, fading image of third return stroke; third appearance of ball-shaped image. Field 7, fourth return stroke (during scan). Field 8, persistence of continuing current ('beading'); fourth appearance of ball-shaped image. Field 9, fading of final image.



and, as has been suggested, may be produced in an analoguous mechanism[6]. Some instances of excessive tortuosity and related re-illuminated beaded processes have also been observed recently in the French research programme[7].

If one assumes that the ball image recorded here is associated with the lightning discharge, then, from a knowledge of the flash distance, the image height may be determined and is found to be approximately 300 m above ground while the apparent image diameter is about 5 m. The latter dimension, although rather large in comparison to many reputed observations of ball lightning, is not inconsistent with recent reports[2,3], but may also be the consequence of the enhanced sensitivity of the camera and the, tendency towards image 'blooming'.

It should also be noted that this particular flash struck the ground about 300 m from a 60 m high aluminium mast. This implies that at least one of the conditions was met for one class of theoretical mechanisms for the formation of ball lightning, that is, those requiring the production of intense clouds of positive space charge in the vicinity of the downward progressing negative leader for example[8], or those requiring field enhanced emission during upward interconnecting positive leader processes from grounded conductive prominences in close proximity to the descending negative leader[9].

In conclusion, however, it should be emphasised that this record is presented mainly for comment and possible interpretation. Clearly, positive identification of this event as a ball lightning event must be tentative until corroborated by further evidence. Meanwhile this observation may improve understanding of the relationship between the lightning discharge and the processes leading to the formation of ball and beaded lightning.

I thank the Council for Scientific and Industrial Research for the opportunity to publish this report.

Open system crystal fractionation and incompatible element variation in basalts

O'HARA[1] has recently proposed an open-system model for the fractional crystallisation of magmas involving continual replenishment of the magma chamber and only partial extraction of the fractionated liquid at each stage. This could produce a series of chemically uniform lavas (such as basalts) with very little resemblance to the primary mantle melt. It is claimed that the model can also explain large variations in the concentrations of incompatible trace elements and their inter-element ratios which would otherwise be ascribed to variable degrees of partial melting or inhomogeneity in the mantle source region. The purpose of this note is to explore the potential and limitations of O'Hara's model in this respect and to test it against the observed variability of Icelandic basalts.

I suggest that three rare earth elements (Ce, Sm and Yb) are especially useful for this purpose. In most solid–liquid equilibria relevant to basalt genesis they range from incompatible to slightly compatible with increasing atomic number. Their relative crystal–liquid partition coefficients are better understood than for many other trace elements although there is some discrepancy between experimentally determined values and estimates based on phenocryst–matrix relationships (Table 1). Lastly there is a large amount of accurate information on the concentrations of these elements in basalts, determined by mass-spectrometric isotope dilution.

The theoretical behaviour of incompatible elements during magmatic processes is reviewed by Hanson[2] to whom the reader is referred for general discussions and relevant equations. Here I have attempted to compute geologically realistic models for the significant factors in basalt magma evolution and the results are plotted in Figs 1 and 2 for Ce against Ce/Sm and Ce/Yb enrichment, relative to concentrations in the source. Brief notes on the details of each calculation follow.

- Partial Melting. An initial source composition of 55% olivine, 25% orthopyroxene, 15% clinopyroxene and 5% garnet was assumed, with these minerals entering the melt in the following relative proportions (melting modes): 10%, 20%, 40% and 30% respectively. After the disappearance of any phase (for example, garnet at 15% partial melting) the melting modes for the remaining minerals were recalculated to 100% in the same relative proportions as before. Partition coefficients used were set 1 in Table 1, since it was felt that these experimentally determined values were more appropriate to equilibrium conditions pertaining during mantle melting. Two curves are shown in the figures—*a* represents batch melting in which the melt remains in equilibrium with the residual solids, *b* is for incremental melting in which each successive 1% of the melt is removed as soon as it forms.
- Zone refining. In this process[3] melt advances by simultaneously assimilating material above it and depositing cumulates behind it, the main variable being the number of relative zone lengths processed, that is, the number of times the magma consumes its own volume. In as far as this process can be visualised at all, it must be restricted to high temperature regions of the mantle through which the basalt magma rises. Consequently the magma was assumed to be a 30% partial melt as in curve *a* above and the bulk partition coefficients for zone refining were calculated as equivalent to 60% olivine, 25% orthopyroxene and 15% clinopyroxene, using set 1 from Table 1. The results are plotted as curve *c*.
- Closed-system crystal fractionation. The parent magma was again assumed to be the 30% partial melt defined above, evolving by crystal fractionation according to the Rayleigh law. To allow for changes which would occur in major element chemistry during this process, it was assumed that the first 30% of solids formed would correspond to peridotite (50% olivine, 30% orthopyroxene and 20% clinopyroxene), the next 40% to olivine–gabbro (30% olivine, 30% clinopyroxene and 40% plagioclase) and the final 30% to anorthosite or granite (30% clinopyroxene, 70% plagioclase). The addition of quartz to the final stage has little effect on relative fractionation of these elements. For this supposed high-level process, the partition coefficients of set 2, based on phenocryst–matrix values, were preferred.
- Open-system crystal fractionation. O'Hara's basic equation (*ibid.* Fig 3) for the enrichment of a trace element in the steady state liquid contains three variables: D, the bulk partition coefficient, X, the proportion of the magma within the chamber which crystallises as cumulates and Y, the proportion of the fractionated magma which is removed and erupted a lava. The relative fractionation of two elements with similar (low) D values depends principally on the ratio X/Y, reaching effective saturation for Ce/Sm at about 10^4

Table 1 Crystal–liquid partition coefficients for basaltic melts

		Olivine	Orthopyroxene	Diopside	Augite	Garnet	Plagioclase

and for Ce/Yb at about 10^3. At the same time, the maximum enrichment of any of these elements increases with X, but is essentially constant below $X = 0.1$. The lines plotted in the figures were thus calculated for $X = 0.01$ by varying X/Y as marked, with the effect of increasing X indicated by the dotted lines. Two cases were considered: with bulk partition coefficients corresponding to each of the first two stages in the closed-system model (that is, peridotitic and olivine–gabbro cumulates) respectively. In both a 30% partial melt was again taken as the primary magma, but for the olivine–gabbro fractionation case it was further assumed that this underwent 30% crystallisation of peridotitic cumulates before arrival at the high-level magma chamber, resulting in a fivefold previous enrichment of Ce, Sm and Yb relative to original source concentration.

The general features of Figs 1 and 2 are essentially similar and are not critically dependent on the mineralogical details of the models. The effect of the choice of partition coefficients is more significant, but it should be noted that the use of set 2 for the high-level crystal fractionation processes enhances their ability to discriminate between Ce and the other two elements. Nevertheless, partial melting is still by far the most efficient mechanism for fractionating Ce/Sm and Ce/Yb ratios, increasing these by factors of about three and 10 respectively for only a 50-fold enrichment of Ce relative to the source. Furthermore, incremental or repeated partial melting is the only process considered capable of producing a magma with lower Ce/Sm and Ce/Yb ratios than the original source material (although repeated zone refining could theoretically have a similar effect). At the other extreme closed-system crystal fractionation is scarcely at all effective at fractionating these elements with respect to each other—even less so than is normally considered for models with constant *D*s. This is because, in the third stage modelled here, removal of heavy rare earth elements in clinopyroxene is largely compensated by the preference of plagioclase for Ce. Zone refining also seems to have a negligible effect except at improbably high values for the number of zone lengths processed (>100). The curves plotted for open-system fractionation are intermediate in their efficiency at fractionating Ce/Sm and Ce/Yb ratios, but the case involving olivine–gabbro cumulates has quite low limiting values (about two times for Ce/Sm and 2.5 times for Ce/Yb).

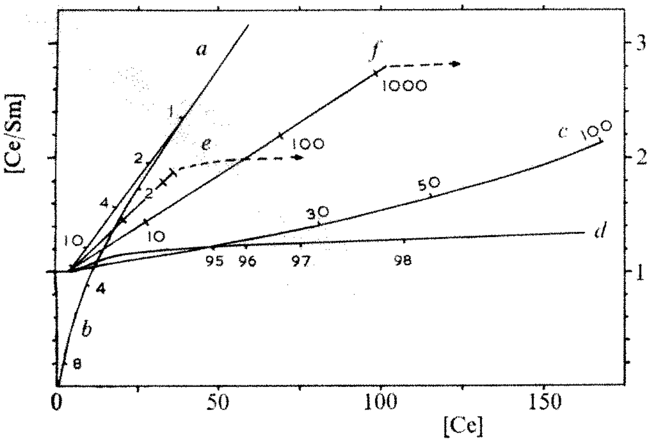

Fig. 1 Ce enrichment against increase in Ce/Sm ratio (both relative to a value of one for the mantle source) for various magmatic processes (see text for details). *a*, Equilibrium batch melting, % melt marked. *b*, Incremental melting (1% increments), % melt marked. *c*, Zone refining in the mantle, no. of relative zone lengths processed marked. *d*, Closed-system crystal fractionation, % crystallisation marked. *e*, Open-system crystal fractionation of olivine–gabbro cumulates according to O'Hara's[1] equation without assimilation, $X = 0.01$, X/Y marked; dotted portion shows effect of increasing X for $X/Y = 10^4$. *f*, As for *e* but with peridotitic cumulates.

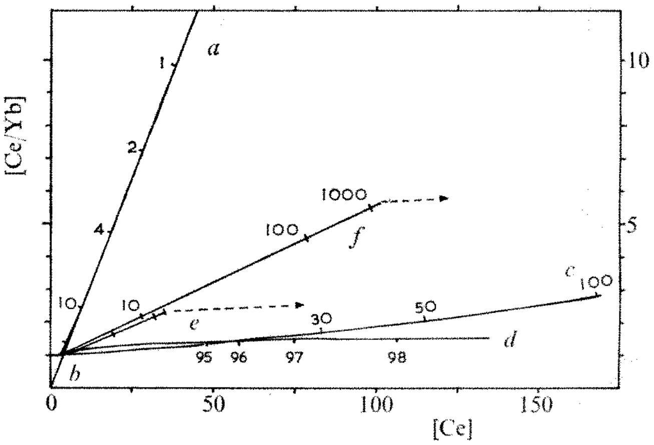

Fig. 2 Ce enrichment against increase in Ce/Yb ratio; see Fig. 1 legend for explanation.

The Icelandic basalt data against which the models are to be tested are summarised in Table 2 under four separate headings, each of which will be considered in turn. In making an initial assessment it is not necessary to know the actual abundance of Ce in the mantle source, although the reader may find it interesting to bear in mind that this is commonly estimated at somewhere between one and three times chondritic abundance.

The first grouping includes all basalts with a common ^{87}Sr/^{86}Sr ratio of 0.70315 (ref. 7), which would thus permit a common source region or parent magma. These are the majority of postglacial mainland basalts and the alkali–olivine basalts of Surtsey and Heimaey. They show a modest increase in Ce/Sm and about a threefold increase in Ce/Yb for an overall sixfold increase in Ce abundance. It is clear that the closed-system crystal fractionation model cannot explain these variations and that zone refining fails for the Ce/Yb variation (except at vanishingly low source abundances and reprocessing of several hundreds of magma volumes). At face value either partial melting or open-system crystal fractionation could be responsible. For example, batch melting of from 5% to 30% of a common source would work with original abundances about six

Table 2 Ce, Sm and Yb variations in Iceland

Grouping	Ranges*		
	Ce	Ce/Sm	Ce/Yb
I Post-glacial tholeiites and alkali basalts with constant Sr/Sr	16–93	1.0–1.6	1.2–3.8
II Reykjanes Ridge tholeiites	7–16	0.5–1.0	0.5–1.2
III All basalts	2–93	0.4–2.3	0.3–7.1
IV All volcanics	16–210	1.0–2.9	1.2–7.4

*All normalised to chondritic abundances.
Data from refs 5–7.

times chondrite. The implied source abundance would reduce to acceptable values if it were allowed that the basalts underwent some crystal fractionation of olivine on their way to the surface (as O'Hara[1] shows must be the case from consideration of their Fe/Mg ratios). Open-system fractionation as modelled here would require initial source abundances lower than those for simple partial melting by a factor of two or more, apparently a point in its favour. However, the olivine–gabbro case can easily be eliminated: in order to discriminate effectively between Ce and Sm, this process would have an even more marked discrimination between trivalent and divalent Eu as a result of the removal of plagioclase. Calculations parallel to those illustrated here show that negative Eu anomalies of at least 30% would be produced, whereas none are actually observed in any Icelandic basalt. This leaves the possibility of open-system fractionation of peridotic cumulates. In assessing whether this is a geologically feasible alternative to the previously proposed idea that these rocks result from variable degrees of partial melting of a common source[5,6], the following factors require re-emphasising. (1) The selection of partition coefficients for these models favours the open-system crystal fractionation case, perhaps unduly. (2) The proportion of magma withdrawn from the magma chamber (Y) must be exceedingly low—certainly 0.1% or less. (3) Failure to achieve the steady state postulated by O'Hara would also reduce the amount of inter-element fractionation. (4) Finally, since the absence of plagioclase fractionation restricts operation of the process to the early stages of evolution of the parent magma, possibly at considerable depths, the distinction between this and other mantle processes such as differential partial melting may be somewhat academic.

The second group shows the incompatible element variation along the Reyjanes Ridge south of Iceland (see also refs 8 and 9). Here a twofold increase in Ce/Sm (slightly more for Ce/Yb) is accompanied by little more than a twofold increase in Ce. Even equilibrium partial melting from a common source cannot account for such a rapid increase, although incremental partial melting could. When the sympathetic variation of ^{87}Sr/^{86}Sr and ^{207}Pb/^{204}Pb ratios is taken into consideration[9–11] the only reasonable explanation is one which invokes inhomogeneity in the mantle source regions, although this could well have resulted from previous extraction of partial melts, which would also explain the low chondrite-normalised Ce/Sm and Ce/Yb ratios.

Comparison with Figs 1 and 2 demonstrates that group III (all Icelandic basalts) and IV (all post-glacial volcanics, including intermediate and acid ones) must be interpreted similarly. Indeed, there is no process realistically capable of causing such high enrichments in Ce as would be implied by the derivation of Icelandic rhyolites from a mantle source which would also yield the light rare earth element-depleted basalts. The conclusion of O'Nions and Gronvold[5] that the acid rocks represent partial melts of a pre-enriched (that is, crustal) source seems well borne out by their significant negative Eu-anomalies.

O'Hara's[1] second line of argument was that if the magma chamber advanced into the oceanic crust, assimilation of basalt which had previously interacted with seawater would very much accentuate enrichment of incompatible elements and could lead to domination of the trace element and isotope chemistry by the characteristics of seawater. This could indeed explain some of the variation in ^{87}Sr/^{86}Sr ratios in, for example, island arcs. It is totally inapplicable to the case of Iceland for the following reasons. Firstly, there is no indication that seawater interaction has ever affected basalts either on the Icelandic mainland or along the Reykjanes Ridge—the observed variations in ^{87}Sr/^{86}Sr being fully confirmed by the evidence of Nd isotopes[12]. In submarine basalts from DSRP Leg 37 which do show evidence of Sr-isotope contamination[13] the Nd isotopes are unaffected[12]. Second, rare earth concentrations are little affected by seawater alteration—the contaminated Leg 37 basalts still have flat-to-light-depleted rare earth element patterns[13] and assimilation of such rocks could not account for enrichment in Ce/Sm or Ce/Yb ratios as displayed by alkali basalts from Iceland or elsewhere.

In conclusion, open-system crystal fractionation as proposed by O'Hara[1] may be a more geologically reasonable model for the modification of mantle-derived magmas than the conventional closed-system model and seems capable of producing greater variability in incompatible trace element ratios. In comparison with partial melting, however, it is severely limited in application to one of the best studied volcanic regions and cannot account for more than a small portion of the observed variation in Icelandic volcanics. In particular, it is not a viable alternative in those cases where mantle inhomogeneity has been previously invoked on the basis of trace element data. The true nature and causes of mantle inhomogeneity beneath Iceland and the Reykjanes Ridge have long been problematical[7–11,14] but, as for mid-ocean ridge segments in general, there is no escaping the need for the redistribution of incompatible trace elements, probably involving a partial melting process at some stage.

Palaeoatmospheric argon in Rhynie chert

THE isotopic compositions and relative abundances of rare gases in the Earth's atmosphere impose rigid constraints on models of atmospheric evolution. Appreciable quantities of argon from the Devonian atmosphere have been extracted from silicified fossil plants and the isotopic composition of this argon implies that the Earth must have been strongly outgassed early in its history.

The fundamentally different origins of ^{40}Ar and ^{36}Ar in the Earth's atmosphere (radiogenic and primordial respectively) make the atmospheric (^{40}Ar/^{36}Ar) ratio a sensitive parameter for investigating the evolution of the Earth's interior. The ($^{40}Ar/^{36}Ar$) ratio in the mantle is also potentially valuable, but atmospheric contamination and the inhomogeneous distribution of potassium within the Earth make the characterisation of this component equivocal, and seriously weaken the argon degassing models which have been based on it[1,2]. The argon in the Earth's atmosphere, unlike that in the mantle, is always well mixed isotopically and represents the time-integrated product of chemical fractionation, radioactive decay and degassing processes within the Earth.

All of the ^{36}Ar in the atmosphere was originally trapped within the Earth when it was first formed. A theoretical value of 2×10^{-4} has been calculated for the ($^{40}Ar/^{36}Ar$) ratio of this primordial argon component[3] and an experimentally determined upper limit of $(1.4\pm0.6)\times10^{-3}$ has been deduced from the analyses of meteorites[4]. Almost all of the ^{40}Ar in the atmosphere (6.54×10^{19} g) is therefore the result of the decay of naturally occurring ^{40}K, the long half life of which must have effectively decoupled the entry of the two isotopes into the atmosphere. If it is assumed that ^{36}Ar was concentrated in the crust/atmosphere more readily than potassium, then the $^{40}Ar/^{36}Ar$ ratio in the atmosphere must have increased monotonically from an initial value of less than unity to the present day ratio of 295.5, the precise shape of the evolution curve depending on the variation of the argon degassing rate constants with time[5,6]. The experimental determination of the shape of this evolution curve should therefore allow argon degassing processes to be critically investigated[7].

The isolation of palaeoatmospheric argon requires the existence of geological samples which (1) are authigenic, (2) incorporated atmospheric argon during their formation, (3) are low in potassium, (4) are very old, (5) are very retentive, and (6) have had a simple geological history. Cherts are among the most suitable samples, but previous attempts to detect palaeoatmospheric argon in Precambrian cherts proved unsuccessful, possibly as a result of their marine origin and complex geological history[7]. The samples selected for analysis in this work were chips of Rhynie chert from the Lower Devonian (about 380 Myr) of Aberdeenshire, Scotland. The Rhynie chert is very low in potassium (100–150 p.p.m.), contains abundant silicified fossils of some of the oldest known land plants and is extremely well preserved[8].

The samples, weighing 50–200 mg, were analysed by the $^{39}Ar/^{40}Ar$ neutron activation method[13] so that corrections for the *in situ* decay of ^{40}K could be applied. No corrections for the neutron-induced production of ^{36}Ar and ^{39}Ar from calcium could be made, based on the ^{37}Ar, because of the long elapse time between irradiation and analysis, but the total amounts of trapped ^{36}Ar were remarkably high ($2–3\times10^{-8}$ ml STP g^{-1}) and the measured calcium content was so low (0.012%) that it could only have reduced the total ($^{40}Ar/^{36}Ar$) ratios by 0.01%, or 0.03. The total ($^{40}Ar/^{36}Ar$) ratios from two unirradiated samples (297.9 ± 1.5 and 295.7 ± 1.1) were in fact less than from the irradiated samples (303.1 ± 3.2 and 299.2 ± 0.8). The ^{36}Ar thermal release patterns from the irradiated samples (5 and 6) were bimodal, most of the ^{36}Ar being released above 1,200 °C, with maxima at 1,350 and 1,420 °C respectively. These very high extraction temperatures strongly suggest that at least the high temperature ^{36}Ar component must be occluded palaeoatmospheric argon. The release patterns for the potassium derived ^{39}Ar were broader, with maxima at slightly lower temperatures (1,220 and 1,350 °C respectively)[9].

The use of the $^{39}Ar/^{40}Ar$ method enables corrections for the ^{40}Ar produced by *in situ* decay of ^{40}K to be applied, so that the isotopic composition of the trapped component can be determined. On a correlation plot of $^{36}Ar/^{40}Ar$ against $^{39}Ar/^{40}Ar$, mixtures of trapped and potassium-derived argon define a mixing line between pure trapped argon ($^{39}Ar/^{40}Ar = 0$) and pure potassium-derived argon $^{36}Ar/^{40}Ar = 0$)[13]. The ($^{39}Ar/^{40}Ar$) ratios were so low that the ($^{40}Ar/^{36}Ar$) ratios from all gas fractions were best corrected individually for ^{40}Ar produced *in situ*, assuming an age of 380 Myr. ($J = 0.0218$, $(^{39}Ar/^{40}Ar)_K = 0.098$). The weighted mean of these corrected ratios for all gas fractions from samples 5 and 6 were (291.0 ± 1.3) and (290.9 ± 1.5) respectively, with an overall weighted mean of (291.0 ± 1.0). The weighted mean atmospheric ratio for all of the low temperature (<1,000 °C) gas fractions (291.7 ± 0.7) was indistinguishable from the total high temperature weighted mean (291.0 ± 1.6), implying that the low temperature atmospheric component may also be ancient, rather than recently absorbed, atmospheric argon.

The high temperature gas fractions are plotted on a three-isotope correlation diagram in Fig. 1. It can be seen that the 1,350 and 1,420 °C extractions from sample 6 do not fall on the mixing line within their analytical errors. Some of this discrepancy may result from calcium interference, but it should be noted that for both samples, the corrected ($^{40}Ar/^{36}Ar$) ratios increase with extraction temperature: 1,220 <1,350 <1,420 °C. This would be expected if argon extraction in the laboratory involves

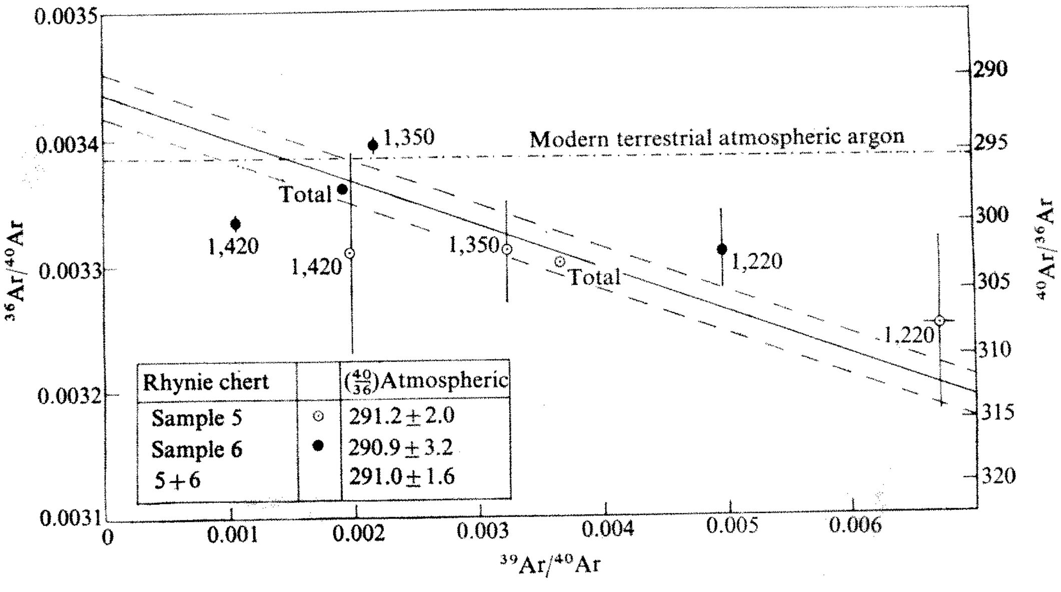

Fig. 1 Isotope correlation plot of ($^{36}Ar/^{40}Ar$) against ($^{39}Ar/^{40}Ar$) for the high temperature ($T >$ 1,000 °C) extractions from two samples of neutron-irradiated Rhynie chert (temperatures in °C). The calculated weighted mean corrected atmospheric ($^{40}Ar/^{36}Ar$) ratio is 291.0 ± 1.6 assuming a gas retention age of 380 Myr. The points marked 'total' represent the arithmetic sums of the high temperature points from each sample and they both fall slightly below the mixing line because the points have not been individually weighted according to their analytical errors.

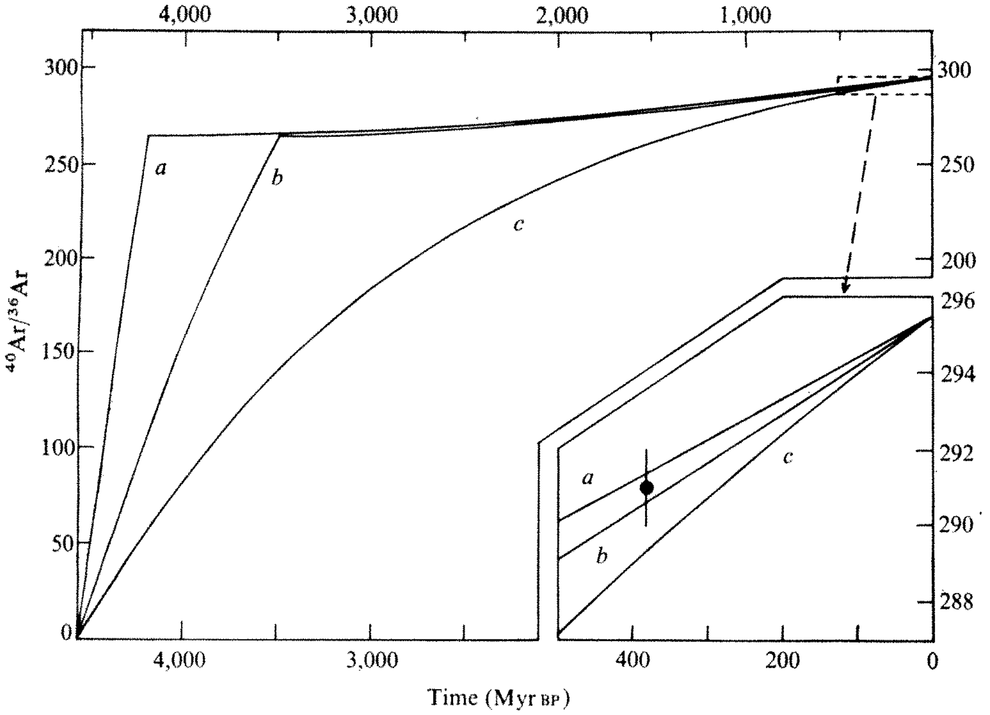

Fig. 2 Evolution curves for the ($^{40}Ar/^{36}Ar$) ratio in the Earth's atmosphere assuming total loss of ^{36}Ar to the atmosphere 4.55×10^9 yr ago. *a*, *b*, Two stage degassing models delimiting a range in potassium content for the Earth from 350–140 p.p.m. and catastrophic degassing periods before 4.2×10^9 and 3.5×10^9 yr ago respectively. *c*, Upper limiting case for single stage degassing models, corresponding to $\alpha \gg \lambda_{40}$ and a potassium content for the Earth of only 75 p.p.m.

mass-dependent diffusion. In these conditions the lighter isotope, ^{36}Ar, may be released more readily than the heavier isotope, ^{40}Ar, giving rise to artificially low initial ($^{40}Ar/^{36}Ar$) ratios. The concordance of the palaeoatmospheric ($^{40}Ar/^{36}Ar$) ratios from the two samples argues against geological diffusive fractionation and both effects could be critically investigated by measuring ($^{38}Ar/^{36}Ar$) ratios in larger, unirradiated samples. But even without the determination of the isotopic ratio of the trapped component, the fact that large amounts of ^{36}Ar are so strongly bound within the sample is in itself a very significant finding.

An atmospheric ($^{40}Ar/^{36}Ar$) ratio of (291.0 ± 1.0) 380 Myr ago imposes a firm constraint on argon degassing models of the Earth. This value is higher than those predicted by all first order degassing models[5,7], unless it is postulated that ^{36}Ar is retained in the mantle preferentially to potassium. The degassing rate constant necessary to account for all of the ^{40}Ar in the present day atmosphere depends on the potassium content of the Earth. The most extreme first order model, for example, predicts a ($^{40}Ar/^{36}Ar$) ratio as high at 289.0, 380 Myr ago but requires a potassium content for the Earth of only 75 p.p.m. (Fig. 2). To explain the slightly higher measured ratio, the degassing constant must have decreased as a function of time. The simplest model consists of two stages, during the first of which the degassing constant was large compared with the decay constant of ^{40}K, as in the extreme single-stage first-order model. Since the termination of this continuous degassing period, the degassing constant has been small. Other simple models might invoke a degassing constant which has decreased linearly, or exponentially, with time. There exists a family of possible two-stage evolution curves for the atmospheric ($^{40}Ar/^{36}Ar$) ratio, depending on what value is taken for the potassium content of the Earth (Fig. 2). This is not known precisely but is constrained by the measured global heat flow. It could be as high as the chondritic value of 880 p.p.m., but the uranium-to-potassium ratios in a wide range of terrestial rocks are remarkably constant (about 10^{-4}) and significantly higher than in chondritic meteorites[10], implying a potassium content of between 250 p.p.m. and 165 p.p.m., or even less for an initially hot Earth[11]. This range in potassium content corresponds to a continuous degassing period which terminated between 4,000 and 3,700 Myr ago. The uncertainty in this time which arises from the error in the measured atmospheric ratio ($< \pm 40$ Myr) is minor compared with that arising from the uncertainty in the potassium content of the Earth and from the limitations inherent in the simplified model. The two-stage evolution curves closely follow one another during the second stage and therefore the determination of the palaeoatmospheric ($^{40}Ar/^{36}Ar$) ratio in suitable Precambrian samples would provide a crucial test for the model.

The determination of the ($^{40}Ar/^{36}Ar$) ratios in the Devonian atmosphere provides further evidence for the early catastrophic degassing of the Earth[14]. Thermal history calculations[11] and lead isotope studies[12] imply early chemical differentiation and crust formation. This crust must then have remained open with respect to argon for about 700 Myr after the formation of the Earth, a process which may have been facilitated by the same intense meteoritic bombardment to which the moon was subjected, a bombardment which terminated about 3,850 Myr ago. The continuous degassing period suggested by this work is certainly consistent with the absence of terrestial rocks with known crystallisation ages much in excess of 3,750 Myr (ref. 15).

I am grateful to G. Turner for discussions and for providing the facilities for this project, and to the Department of Geology, University of Sheffield for the samples and calcium analysis. The work was made possible by a grant from the Natural Environment Research Council (GR/3/1715) and support for the neutron irradiation came from the Science Research Council (B/RG/5624.8).

Lead isotope measurements from the oldest recognised Lewisian gneisses of north-west Scotland

No isotope ages exceeding ~2,800 Myr have yet been reported from Lewisian gneisses. Furthermore, there is no published isotopic evidence suggesting that Lewisian gneisses incorporate a significant proportion of much older, re-worked sialic crust. Recently, Davies[1] has interpreted field evidence from small, discordant amphibolite bodies as indicating a pre-2,800-Myr history of the Lewisian Complex in the type localities of Scourie and Laxford, Sutherland, which is directly comparable with that of the Godthaab area of West Greenland. He has proposed that equivalents of the ~3,700-Myr-old Amîtsoq gneisses and ~2,800-Myr-old Nûk gneisses can be distinguished, on the tentative assumption that the basic bodies are the equivalents of the Ameralik dykes[2–4]. This paper tests this hypothesis using Pb isotopes.

In Table 1, we present 12 whole rock Pb isotope analyses on the Older ('Uamhaig') gneisses of Davies[1], as well as eight analyses on other nearby granulite gneisses within the type Scourian Complex[5]. The Older gneiss samples were supplied by, or collected in collaboration with, Dr F. B. Davies. Almost all analysed samples are one- or two-pyroxene quartzofeldspathic gneisses, some of which exhibit incipient retrogression into amphibolite facies. Several samples contain hornblende, garnet or biotite.

Pb was extracted from whole rock powders by the dissolution-electrodeposition procedure of Arden and Gale[6]. Blanks were between ~0.1 and 0.5% of total Pb extracted, averaging 10 ng per dissolution. Isotopic analyses were made on a 12-inch solid-source mass spectrometer, using silica gel–phosphoric acid activator on single Re filaments. Decay constants for ^{238}U and ^{235}U were taken as 1.551×10^{-10} yr^{-1} and 9.85×10^{-10} yr^{-1} respectively[7]. (Previous publications from this laboratory used the older recommended values of 1.537×10^{-10} yr^{-1} and 9.72×10^{-10} yr^{-1}).

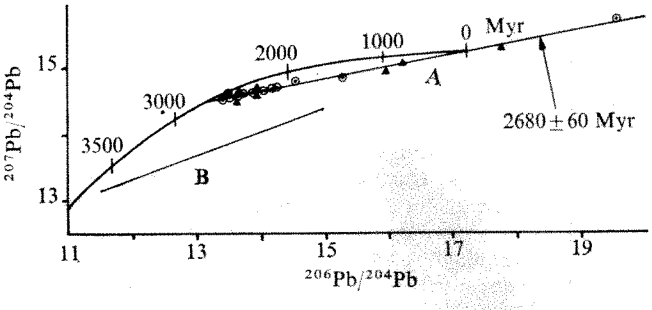

Fig. 1 Pb/Pb plot of analytical data (line A). ⊙, Older gneiss group of Davies[1]; ▲, Scourie gneisses. For comparison, line B is the maximum range of present-day measured values for ~3,700-Myr-old Amitsoq gneisses of West Greenland.

^{207}Pb/^{204}Pb and ^{206}Pb/^{204}Pb ratios are plotted in Fig. 1, line A. The data points define an isochron, but to achieve perfect fit analytical errors must be magnified by three. The isochron yields an age of 2860±60 Myr (2σ), which agrees well with other recent age determinations on Scourian rocks[8–10]. The ^{238}U/^{204}Pb ratio (μ_1) for the source region of the gneisses was 7.7—the value taken for plotting the Pb isotope primary growth curve in Fig. 1. This value is well within the range typical of upper mantle source regions. There is also a good correlation (not plotted) between ^{208}Pb/^{204}Pb and ^{206}Pb/^{204}Pb data, yielding a value of 3.1 for the Th/U ratio of the gneisses (correlation coefficient = 0.97). This is within the characteristic range for many primary igneous rocks.

For comparison, line B in Fig. 1 represents the maximum range of measured present-day Pb isotope compositions for ~3,700-Myr-old Amîtsoq gneisses of West Greenland (ref. 11, 12 and unpublished data) which include the most unradiogenic terrestrial Pb isotope ratios yet reported. It is evident that the analysed gneisses (Table 1) contain no detectable Pb derived from a source similar to Amîtsoq gneisses. At 2,800 Myr ago, Pb in Amîtsoq gneisses was even less radiogenic than today and nowhere near the initial Pb isotope composition of any known Lewisian gneisses (Fig. 1). We believe that this argues strongly against the

presence of such ancient sialic crust within, or beneath, this part of north-west Scotland. In agreement with earlier work[13] we postulate that the presumed igneous precursors of Scourian gneisses separated from upper mantle or basic lithosphere not more than ~100–200 Myr before the measured date.

Whilst these findings do not necessarily contradict the field evidence of Davies[1] regarding the relative ages of different gneiss groups, they suggest a much more condensed time sequence possibly similar to that of the Nûk gneisses of West Greenland[4] and render detailed Archaean correlation between north-west Scotland and West Greenland implausible.

We thank Dr F. B. Davies for invaluable cooperation, as well as Dr P. N. Taylor and Professor J. V. Watson for critical comments. Messrs R. Goodwin and M. Humm provided skilled technical assistance. The work at Oxford is supported by the Natural Environment Research Council.

Giant late Jurassic sabkhas of Arabian Tethys

THE discovery that anhydrite–gypsusm evaporites with characteristic textures are forming today in the shallow subsurface of supratidal coastal sabkhas and in continental sabkhas from Arabia[1,2] has revolutionised the interpretation of ancient evaporite sucessions. Several ancient evaporite basins, of great economic importance, lately regarded as former hypersaline lagoons or barred basins, have been recently re-interpreted as the deposits of former prograding sabkha plains[3,4]. In this note we demonstrate that late-Jurassic evaporitic sulphates and minor chlorides of Saudi Arabia, Iran, Iraq, Kuwait, Trucial States, Yemen and Aden were deposited on giant sabkhas ($>2\times10^6$ km²) on the southern margin of the former Tethys Ocean. At their maximum extent in Tithonian times these inferred sabkhas seem to have been among the largest yet discovered. The evaporitic facies throw some light on the evolution of giant sabkha plains. In addition the sabkha plains form the caprocks to some of the world's most prolific oil reservoirs[5–7], so that understanding of evaporite genesis is of outstanding economic interest for Middle East stratigraphic studies.

In Saudi Arabia (Figs 1, 2), anhydrite members occur at four main horizons in the Arab and Hith Formations of late Kimmeridgian to Tithonian age[5,6]. The uppermost Hith anhydrite occurs in Trucial Coast and Iranian subcrops[8–10] and finds correlatives in the Gottnia anhydrite of Iraq, Kuwait and north-west Iran[7,8,11] (Figs 1,2). The Arab-Hith Formations have been regarded as slightly younger than the Amran Group evaporites of Yemen and Aden[9] but these latter are poorly dated, being overlain conformably by the Upper Tithonian Marine limestones. Faunal data in ref. 9 cannot rule out the possibility that the Amran evaporites may be late Kimmeridigian to middle Tithonian in age.

Investigations of the Arab–Hith evaporites in the Saudi surface outcrops are hindered by massive Tertiary dissolution, while in the subcrop there are, as yet, only generalised thickness data from oil exploration coreholes[12]. At Dahl Hith, however, 32 km south-east of Riyadh, the type section of the Hith anhydrite occurs (Fig. 2) in a deep dissolution cavern where we have recently documented clear evidence that sabkha-type facies are present, with nodular, 'chicken-mesh' aggregates and enterolithic veins in quartz silt-rich, dolomitised grainstone hosts. Crudely layered anhydrite units with disrupted fabrics, resedimented clasts and laterally persistent anhydrite–dolomite varves also occur. The Arab-A carbonate member consists of dolomitised pelletal grainstones showing traces of large scale cross stratification. The Arab–B evaporite member at the base of the section shows particularly fine nodular and layered anhydrite. At outcrop, sections in the basal Arab-D evaporites are rare in the collapse breccia zone, but at Wadi Nisah (Fig. 1) we have found bedded remnants of chicken-mesh anhydrite, now calcitised, in a dedolomitic calcite matrix. Traced eastwards in the subsurface, the Arab

Fig. 1 Map to show principal surface and subsurface sections used to delimit the approximate near-maximum extent of the Arabian late Jurassic sabkhas during Hith Anhydrite times (after data in refs 5–12, 16–19 and unpublished data). Stippled area indicates maximum development of porous lime sands during Arab-D times[16] (see Fig. 2). These now form the major Saudi oil reservoirs.

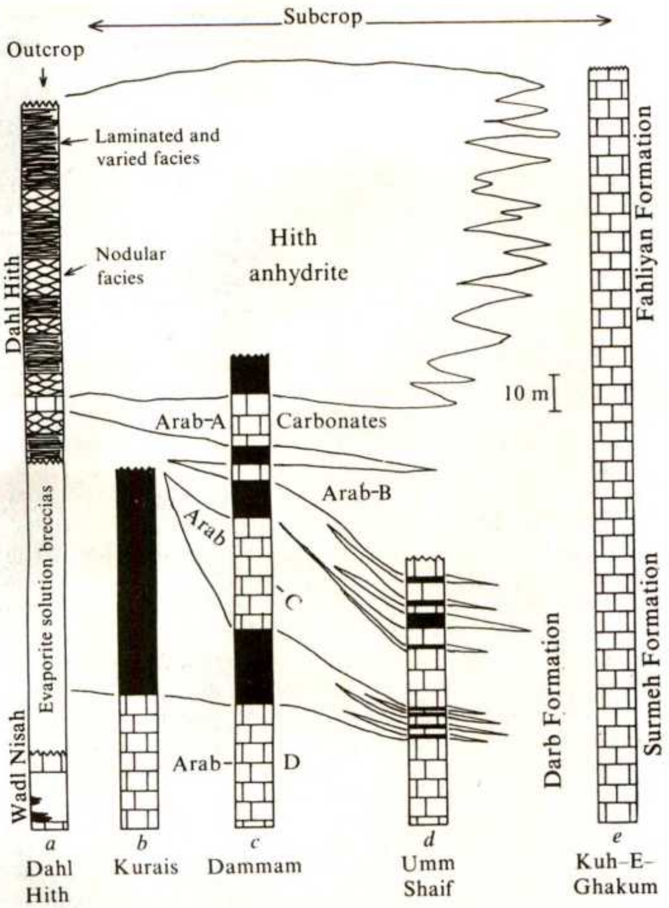

Fig. 2 Major facies changes in the Arab/Hith Formations and their correlatives in the Gulf and Iran to show general eastwards tongueing-out of evaporites away from the landward parts of the supposed sabkhas in central Arabia. Location of sections in Fig. 1. (Data for *a*, authors' results; *b*, *c*, refs 5, 6, 12; *d*, ref. 10; *e*, ref. 8). Note that anhydrite in section *d* is of nodular type only.

Formation anhydrite members thin progressively towards the Persian Gulf while the interbedded grainstones of presumed offshore bar origin tend to thicken[5,6,12] (Fig. 2) until they thin on to the Surmeh shelf of the south-eastern Gulf and Iran[8]. In the Umm Shaif field of offshore Abu Dhabi the Dharb Formation shows many thin sabkha cycles and is correlated with part of the Arab Formation in the Saudi and Qatar subcrops[10]. As the Hith anhydrite is traced eastwards into Iran it is replaced by partly dolomitised offshore marine carbonates of the Surmeh Group[8] (Fig. 2).

From the above discussion it would seem that sabkha progradation occurred repeatedly from west to east during Upper Kimmeridgian and Tithonian times, that is, from the core of the Arabian shield towards the shelf margin of Arabian Tethys (>1,200 km). Sabkha progradation was followed in each depositional cycle by marine transgression. Sections in the present westernmost outcrops thus contain evaporitic facies precipitated progressively further from the Tethyan coast as time proceeded during each progradational episode. Following Walther's Law, therefore, the vertical facies sequence within each evaporite cycle should demonstrate how evaporitic environments evolved with time. In eastern areas the thin sabkha cycles such as seen in the Umm Shaif field[10] represent more or less precise analogues to the deposits of modern coastal sabkhas which have only been developing since the post-glacial standstill some 4,000–5,000 years BP (ref. 2). In this area repeated transgression followed by carbonate deposition and then sabkha progradation has given rise to many thin sabkha cycles. To the west, however, in the outcrops of the Arab–Hith Formations at Dahl Hith, there are repeated thicker rhythms of nodular anhydrite, sometimes with signs of a carbonate matrix, followed by laminated and varved anhydrite. It is very noticeable that the carbonate members, dominant in the Arabian–Trucial States coastal areas, thin progressively westwards as well (Fig. 2). Sabkha cycles with hitherto unexplained layered and varved upper members are also recorded from the Permian of Cumbria, England[13].

We infer that as coastal sabkhas prograde out to some critical width subsurface anhydrite nodule growth ceases and the interior sabkha plains are converted in some way into periodically emergent playas giving rise to laminated and varved anhydrite. Exactly how this process occurs is at present unclear. The evidence of resedimented anhydrite clasts, and buckled and broken anhydrite laminae indicate that the postulated brine pools were frequently dried up. Scattered quartz grains may indicate some aeolian input into the sabkha plains but we stress that the more important features of continental sabkhas as discussed by Kinsman[2], such as remnant aeolian dune sets, deflation surfaces and adhesion ripples are absent. As Kinsman has noted[2], a broad prograding sabkha surface will tend to be depressed below the base level of erosion as basin downwarp continues. When, as in the present case, there is an absence of aeolian deposition a broad depression would result which might receive brine input due to (1) seepage from the local brine table, (2) marine recharge, possibly from channel courses linked seawards to marine areas, (3) surface drainage from continental hinterlands, (4) continental brine migration, likely to be most important relatively close to the landward sabkha margin[14]. The source of such brines is clearly of the utmost importance and deserves further study. In such interior parts of giant sabkha plains sodium- and potasssium-rich bitterns should also occur, their formation being aided by the fractionation process outlined by Smith[15] for the Permian Zechstein evaporites. Potash is not known in the Arabian evaporites, but extensive halite occurs in Kuwait[7], Aden[9] and the Saudi Rub al'Khali[16] basin. These areas of chloride precipitation, not usually furthest from the presumed Tethyan shoreline, may represent areas of the Arabian platform undergoing greatest subsidence[16]. Associated organic-rich, sometimes foetid micritic limestones lack the well-washed skeletal constituents of the typical Arab Formation carbonates[16] and may be ascribed to rapidly subsiding, possibly partly euxinic, brine-filled basinal areas within the Arabian platform.

As Kinsman[2] has pointed out, the rate of shoreline regression in the modern Trucial Coast, has been about 1–2 m yr^{-1} during the past 4,000–5,000 years. Over 10^6 years a sabkha could develop 1,000–2,000 km wide, as postulated above. A minimum of four periods of major late Jurassic sabkha progradation is recorded in the Arab/Hith Formations in the western Saudi areas. These deposits together probably formed over a total of about 10^7 yr, so it would be entirely in order for individual sabkha progradation to have occurred over periods of about 2×10^6 yr.

Our palaeogeographical sketch (Fig. 3) shows the maximum likely extent of the giant Arabian sabkhas in relation to a late-Jurassic restoration of the continental plates that formerly bounded the Tethyan ocean. It is clear that the coastal plain was bounded on three sides by areas undergoing normal shallow marine carbonate and clastic sedimentation. Repeated marine transgression over the structurally simple Arabian platform, giving rise to sourcerocks and potential oil reservoirs, was thus followed at least four times by massive eastward coastal progradation and sabkha evaporite formation during late Jurassic times. Detailed sedimentological analysis of these evaporites will follow in a later contribution.

Contact angle and film jumps

THE mechanism of capillary rise in a random sphere packing is such that, depending on the absolute value of the wetting- or contact-angle, θ, at equilibrium either a saturation gradient, widest for $\theta = 0$, is observed, or a sharp front between the saturated and the dry part of the porous medium, above some critical value of θ (ref. 1). We present here another partition in the phenomenological description of capillary rise for systems which have $\theta > 0$. There are systems in which θ remains constant and others in which θ decreases during capillary rise. In particular, attention is drawn to an uncommon hypothesis that can explain a decrease in θ. Given the nature of the absorption isotherm in the neighbourhood of saturation, small variations in vapour pressure may induce discontinuous film thickness jumps on a microscopic scale, which may display itself macroscopically as a changing contact angle.

Only capillary rise of organic liquids in random packings of glass beads is considered. For capillary rise of a sharp liquid front in a packing[3]

$$\mathrm{d}h/\mathrm{d}t = (k/h)(h_c - h) \qquad (1)$$

where h is the height of capillary rise at time t, h_c the (capillarity) driving force, and k the Kozeny–Carman permeability. The value of k depends only on the packing and the viscosity and the density of the liquid. The value of h_c depends on the geometry of the pore space, the liquid surface tension, σ, and the contact angle. Hence, for a combination of a solid packing and a liquid, a straight line should be observed when $\mathrm{d}h/\mathrm{d}t$ is plotted against $1/h$—that is, the velocity curve is straight. The value of k can be calculated for random sphere packings. The value of h_c can then be calculated from equation (1). In our experiments[4] the emphasis was on the variation of many practical relevant parameters, not on the purity or cleanliness of the substances. Capillary rise was observed for *n*-hexane, *n*-heptane, paraffin oil (medicinal), toluene, ethanol, *n*-octanol, glycol, acetone, carbon tetrachloride. α-bromonaphthaline and dichloroacetic acid. Glass spheres of different chemical constitution were used. For some glass surfaces and some liquids θ seemed to be zero. In that case a saturation gradient is formed at equilibrium[1,5]. Before the saturation gradient is formed, equation (1) is obeyed in that the velocity curve is linear and k agrees with theory, such behaviour is called rapid capillary rise. When $\theta \neq 0$ equation (1) is rarely obeyed. An example is given in Fig. 1 for paraffin oil; when $\theta \gg 0$ no saturation gradient is formed at equilibrium[1,5].

When the velocity curve is concave towards the $\mathrm{d}h/\mathrm{d}t$ axis, the $\mathrm{d}h/\mathrm{d}t$ change is slower than equation (1) predicts. This is called slow capillary rise. (Hence 'slow' and 'rapid' do not refer to the absolute value of the capillary rise. A slowly moving viscous liquid such as paraffin oil displays rapid rise. A rapidly moving thin liquid such as hexane may display slow rise, see Fig. 1. Slow capillary rise has been observed for all liquids mentioned above and at some glass surfaces.

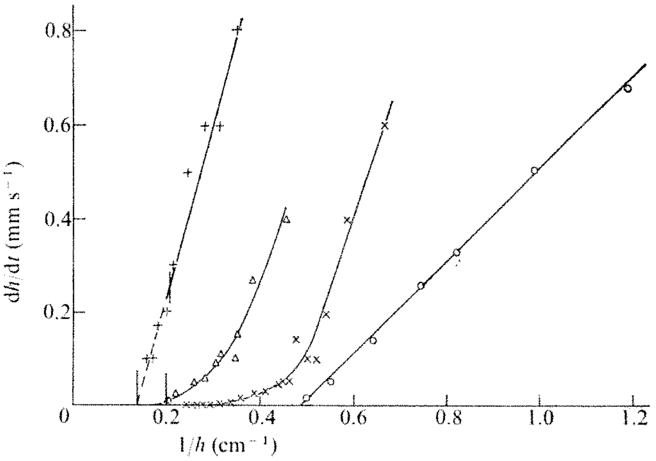

Fig. 1 Capillary rise experiments are carried out by submerging a packing of glass beads 2 mm below a liquid surface, which is kept at a constant level. The packing is contained by a glass tube and supported by a glass filter, or it is slightly sintered, in which case no support is needed. The packing is prepared using a controlled deposition and vibration technique. The homogeneity is checked by means of X-ray absorption. The capillary rise is observed visually or by X-rays. When there is a sharp liquid front both methods give the same result. The packing, X-ray absorption, and sintering techniques have been described in detail elsewhere[2]. The capillary rise of hexane +, △, ×, and paraffin oil ○ in a packing of 300–400 μm sodaglass beads is depicted: ○ and +, rapid rise; △ and ×, slow rise; + and △, saturation gradient at equilibrium; ○, sharp front at equilibrium (coordinates on vertical scale have to be multiplied by 100).

Reports elsewhere support the fact that slow capillary rise corresponds to a decreasing contact angle during capillary rise[4]. Although equation (1) applies formally in that the movement of the liquid front is caused by the pressure gradient $(h_c - h)/h$ and constant resistance to flow, k, the observed dh/dt is determined by the change in h_c. We carried out many experiments to check that the slow capillary rise was not due to secondary factors such as a change in packing structure, air entrapment, capillary condensation, or evaporation. Becuase the geometry is constant, for any liquid k is constant and h_c depends only on the contact angle and the liquid surface tension, σ. Further, it seems impossible that slow rise is due to an increasing σ (θ being constant), because this would imply for the curves of hexane (which has $\sigma = 18$ dyn cm^{-1}) that at the beginning of capillary rise σ is about 8 dyn cm^{-1}.

It is not possible to discuss here the numerous hypotheses that might explain a decreasing θ. The following possibilities were considered: unknown compounds on the solid surface, in the liquid, from the air, etc.; heterogeneity of the surface (geometric or energetic); (electro) chemical changes of the surface (penetration, solution); change in film properties (formation, displacement, (selective) evaporation); capillary condensation. It is almost impossible to design experiments that discriminate between these hypotheses. For example, with toluene as a wetting liquid, *inter alia*, the following parameters were varied—glass composition: lead–, soda–, boro–, silicate–, and aluminosilicate–glass; numerous treatments, including vacuum, heat, acids (also hydrogen fluoride), NaOH, detergents; various rinsing and drying methods (including those which yield $\theta = 0$ for water on glass plates); liquid: from different suppliers, degassed, freshly distilled, dried over molecular sieves, dissolved compounds added of higher and lower surface tension and or vapour pressure; vapour: in the absence of air, evaporating from liquid surface, with a gas pressure opposing capillary rise [$(h_c - h - \Delta P)$ instead of $(h_c - h)$ in equation (1)].

Although these variables sometimes had a small effect on the kinetics of rise, in no case was rapid rise observed, in the sense of obeying equation (1). Moreover, an increasing contact angle was never observed (This would be shown by k being higher than the theoretical value). Glass surfaces yielding $\theta = 0$, could be changed (irreversibly) into surfaces yielding $\theta > 0$ and slow rise, by applying surface treatment. Therefore, it is concluded that none of the hypotheses receives significant support. A more interesting but more speculative hypothesis to explain the general phenomena of decreasing contact angles follows.

When $\theta = 0$, at equilibrium, after capillary rise, the adsorbed film, a thin macroscopic wetting film, and the meniscus are in equilibrium. When $\theta > 0$ there is some kind of discontinuity between the bulk liquid and the adsorbed film. Although straightforward and mentioned by Freundlich[6] in 1922, it is seldom realised that, if $\theta \neq 0$, the adsorption isotherm should cut the $\varphi = 1$ axis one or more times (φ is the relative vapour pressure, p_v/p_s).

One way to describe the nature of the adsorption film in the region $\varphi = 1$ is by using the concept of disjoining pressure[7], p_d, defined as $l\,d\mu/dl$, with l the thickness of the film (defined for molecular as well as macroscopic films) and μ the chemical potential per unit volume of adsorbed film. The film is thermodynamically stable if $(\partial\mu/\partial l)_T > 0$. If p_d is positive for all l, $\theta = 0$ for all values of l. If $\theta > 0$, there is a region of unstable film thickness for which p_d is negative. This means that at some vapour pressures, in particular at p_s, different θ, corresponding to different l are possible. Hence, small variations in p_v (or μ for a non-homogeneous multicomponent system) may cause discontinuous changes in l, called film jumps.

Many strange phenomena become more intelligible when it is realised that variations in vapour pressure may cause discontinuous jumps in the film thickness and hence the contact angle. The best examples are found amongst the experiments of Bangham *et al.*[8]— for example θ for a drop of benzene placed on a micasurface decreased when brought under the influence of a jet of supersaturated benzene vapour. Further, it seems possible that some Marangoni phenomena in which a solid surface is present are in fact caused by film jumps.

During capillary rise small fluctuations in temperature (or concentration of unknown compounds) cause local changes in vapour pressure (or thermodynamic film potential) and therefore possibly film jumps, and hence a change in θ. This causes a minor local increase in capillary rise, which may trigger the nearest cavity (or 'pore', refs 1, 5) to be filled, which gives a minor rise of the whole liquid–vapour interphase. A local increase of θ, will not decrease the macroscopic height of the liquid front, because the curvature at which a cavity drains is much higher than the curvature at which it fills (structural hysteresis). This may explain why until now we have not observed slow rise in cylindrical capillaries. (Not many data are available, however, because nearly always $\theta = 0$.) The fact that paraffin oil does not show the behaviour described may correspond to the observation by Hardy[9] that there is almost no adsorption film in this case.

Although we realise that we have not given very strong support for the film jump hypothesis, we think it is worth consideration. Wetting phenomena have some role or other in almost any scientific discipline. We would appreciate any information about other phenomena or considerations that have a bearing on this subject.

Palaeoecological investigations of a site at Hampstead Heath, London

OUR understanding of the vegetational history of Britain is based mainly on studies of peat-bogs, lake and kettlehole infills[1]: away from areas where such deposits exist, there is a paucity of information[2]. A multidisciplinary investigation of a deposit associated with a Mesolithic site on Hampstead Heath, North London, is providing rare evidence about man's effect on the vegetational succession of south-east England. The pollen spectrum indicates that *Tilia* rich forest existed until the elm decline, followed by continuing clearance episodes and heath formation. Seeds and beetle remains, which provide more precise information on local conditions, confirm the overall pattern of change from natural forest to cleared areas used for cultivation and grazing. The Mesolithic site of West Heath, Hampstead (TQ2566 8676), is being excavated by the Hendon and District Archaeological Society under the direction of Mr D. Collins[3]. The site stands on dry, acid Bagshot Sands, but environmental investigations have been carried out at West Heath Spa, a boggy area about 300 m to the south-east, where permanent waterlogging is maintained by a chalybeate spring. At this spot, samples for pollen, seed and insect analyses were collected at 5-cm intervals from below the modern root layer to a depth of 130 cm. Results of these studies are briefly described here.

A pollen diagram (Fig. 1) has been drawn up from

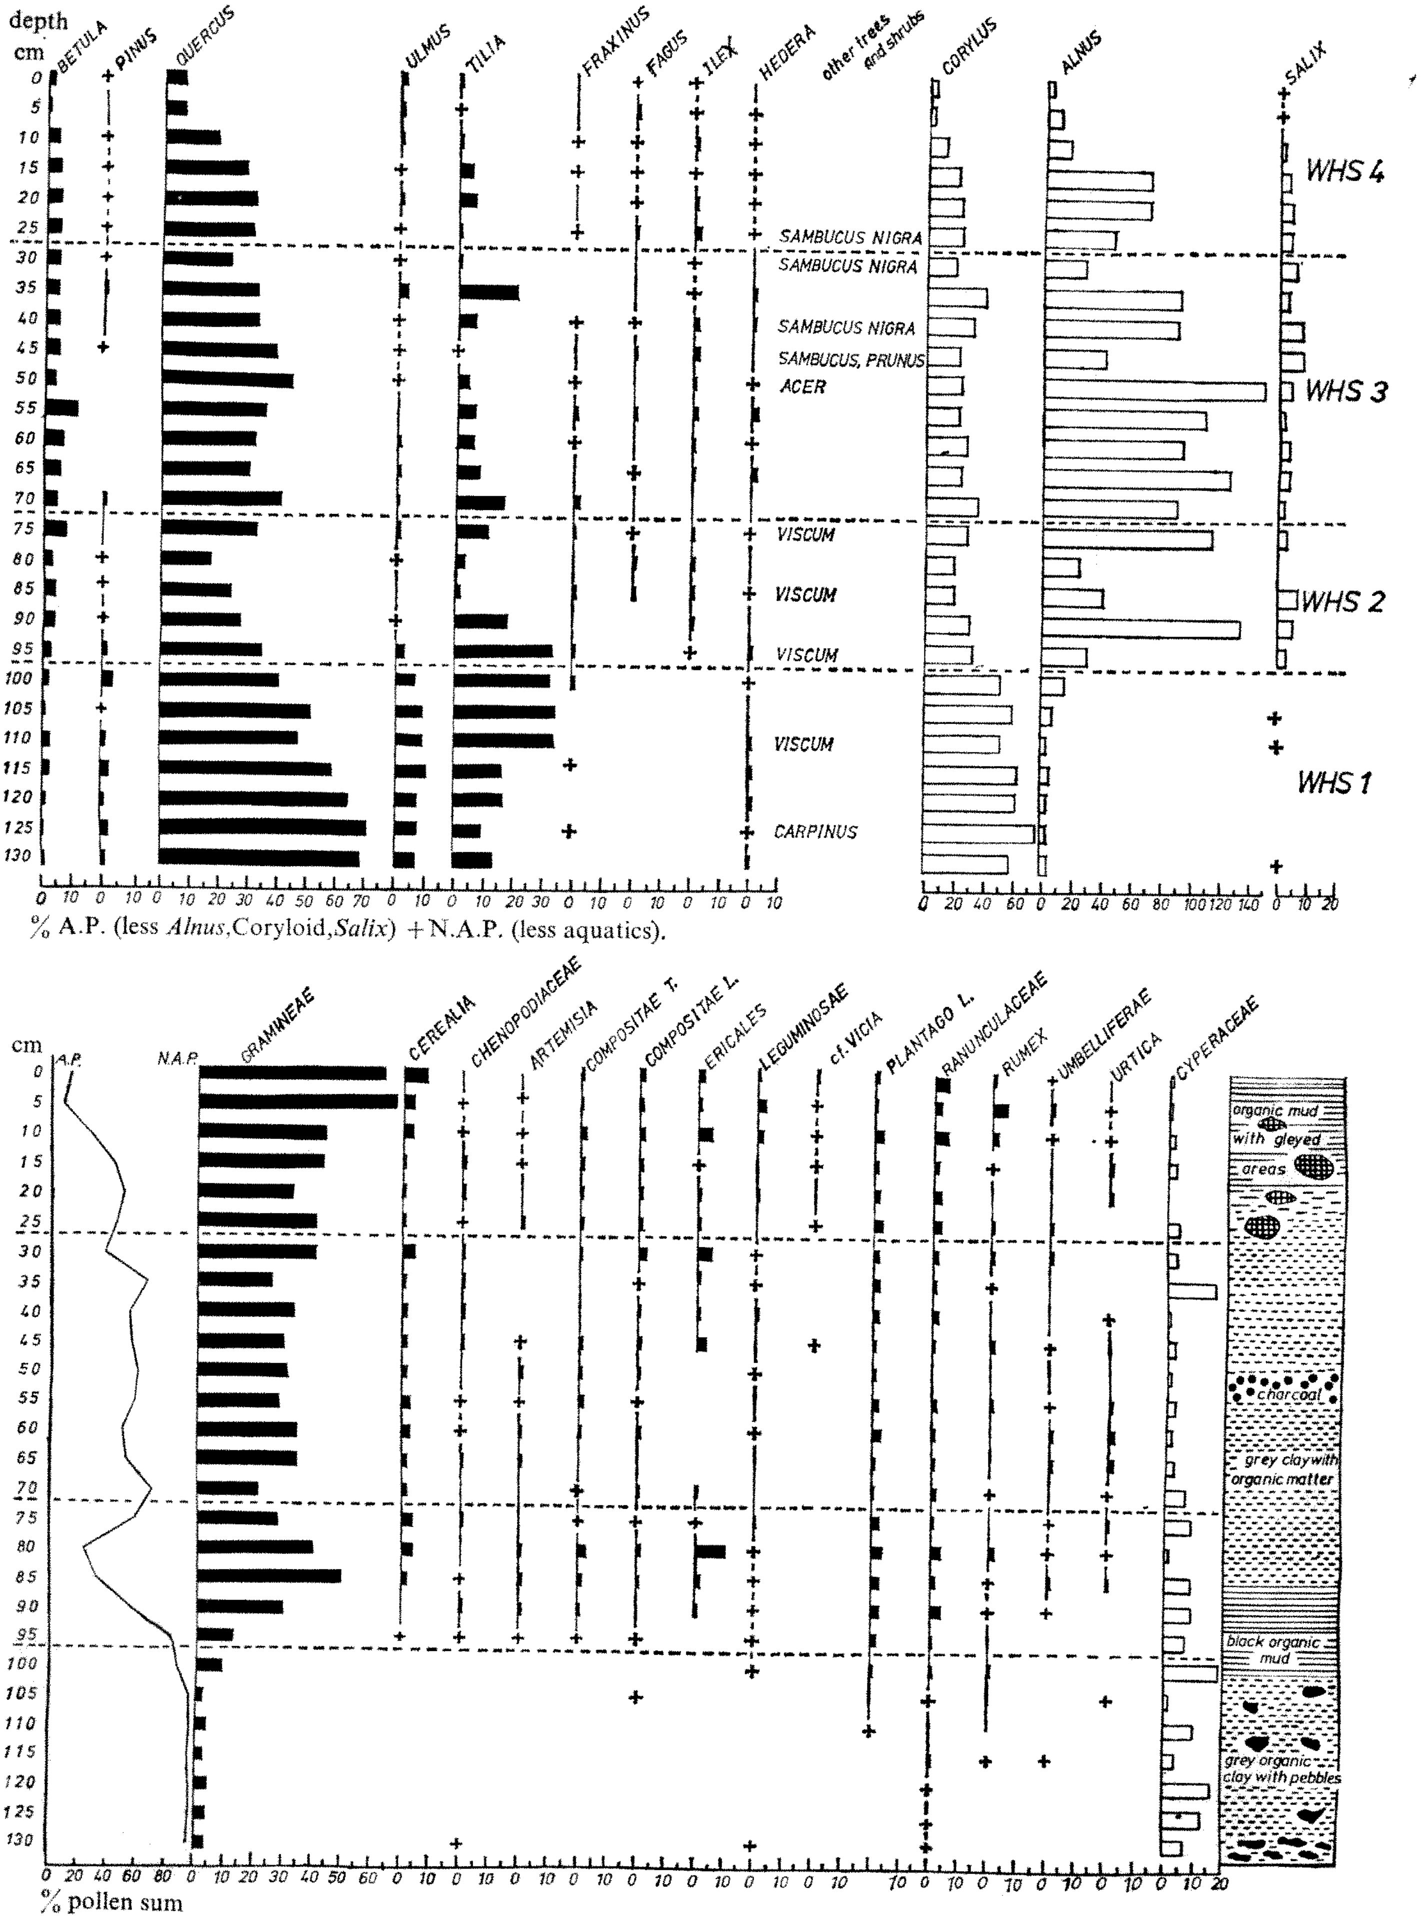

Fig. 1 Pollen diagram for West Heath Spa. Pollen counts of 400–900 grains were taken for each 5-cm layer.

counts of 400–900 pollen grains for each 5-cm layer. It can be divided into four zones of which 130–100 cm (WHS 1) corresponds to Zone VIIa, 100–75 cm (WHS 2) and 75–30 cm (WHS 3) correspond to VIIb and 30–0 cm (WHS 4) corresponds to VIII. These changes are reflected by the seed and beetle assemblages.

Quercus (oak) is the most commonly represented pollen type in WHS 1 but, *Tilia* (lime), an insect-pollinated tree, is believed to be under-represented in the pollen rain[1], and at West Heath Spa, its substantial pollen record seems to indicate a forest composed predominantly of lime. The abundance of lime pollen, seen also at Shustoke, Warwickshire[4], Butterbump, Lincoln (J.G., unpublished), and Epping Forest (P. A. Moxey and P. M. Oxford, personal communication) shows that contrary to earlier concepts of mixed oak forest during the Atlantic, lime was probably the dominant forest tree in the Midlands, southern and eastern England. The high values of oak and *Corylus* (hazel) compared with *Alnus* (alder) are probably due to the Spa's situation, an isolated marsh rather than a large wetland with surrounding alder carr. Amongst wood-dependent beetles, the commonest is *Ernoporus caucasicus* Lind., a small lime-feeder which has been found in numbers in deposits of this age[4], but was first captured in Britain as recently as 1954 (ref. 5). Other scolytids include *Kissophagus hederae* (Schmidt.), an ivy feeder, and the only host specific species in this country[6], and *Xyleborus xylegraphus* (Say) which is found on pines as well as several deciduous trees. Also present are the oak leaf-miner *Rhynchaenus quercus* (L.), the holly-feeding cerambycid *Pogonocherus hispidus* (L.) and the small anobiid *Gastrallus immarginatus* (Mull.)—a typical old forest species.

Delineating the boundary between Zone VIIa/VIIb, the pollen values for elm decrease dramatically and appearing for the first time are Cerealia and ruderals such as *Plantago lanceolata* L. (ribwort plantain), which are associated with the activities of man. Accompanying this classic elm decline are falls in the level of oak and lime and *Corylus* pollen. The appearance of *Fagus* (beech) in WHS 2 and maximum frequencies of *Ilex* (holly) in WHS 3 might indicate their expansion into areas of previously closed forest. The appearance of Ericales pollen denotes the start of heath formation. The insect fauna of WHS 2 contains a smaller percentage of tree obligate species than lower samples, although records of decaying wood inhabitants such as *Eremotes ater* (L.) are noteworthy, particularly if, as Rackham suggests, primitive man was unable to clear away large stumps and trunks of felled trees[7]. Both seeds and beetles reflect increased wetness leading to pond formation. Aquatic Ranunculaceae including *Ranunculus flammula* L. and *R.* (*Batrachium*) spp. are present together with *Isolepis setacea* (L.) R.Br. (bristle scirpus) and *Lycopus europaeus* L. (gypsywort). Seeds of *Pedicularis sylvatica* L. (lousewort) have been recorded for the first time in a Zone VIIb deposit. The beetle fauna is dominated by aquatic species of *Helophorus, Hydrochus* and *Hydraena.*

After the elm decline, a semi-stable state is maintained in WHS 3, perhaps by a succession of clearance episodes, the concentration of charcoal suggesting the use of fire. Renewed heath formation is inferred from the reappearance of Ericales. A new faunal element, dung beetles of the *Aphodius, Onthophagus* and *Geotrupes* genera, which appears at 80 cm, probably indicates grazing by herbivorous animals in the grasslands.

The final pollen zone, defined by a further steep fall in tree pollen, including *Corylus* and *Alnus,* with a corresponding rise in herbaceous pollen, is characteristic of pollen diagrams from the Iron age onwards. A similar pollen diagram has been drawn up from New Palace Yard, a London site dated to the Iron age (J.G. and S. Limbrey, unpublished). The continuing record of Gramineae, Cerealia, Leguminosae, *Plantago* and *Rumex* (dock) indicates further cultivation, and Ericales are present throughout. *Sirodendron cylindricum* (L.), is one of the very scarce wood-dependent beetles from these upper samples, most of the species require open land or waterside habitats, such as *Hydrothassa marginella* (L.) and *Plateumaris discolor* (Panz.), a cottongrass-feeder which favours acidic habitats.

Further investigation of all the organic remains at West Heath Spa should provide important evidence on several aspects of the prehistory of the area. It should be possible to determine closely the environment of the Mesolithic habitation site, to investigate man's increasing modification of the landscape after the elm decline and finally, to evaluate the anthropogenic factor in the formation of Hampstead Heath.

We thank Mr D. Collins for useful discussions.

Summer food as the factor limiting roe deer population size

THE sizes of unexploited populations of roe deer (*Capreolus capreolus*) are regulated by spring migration. Individuals which have been able to establish a territory (bucks) or home range (does) force all other animals to move out of the habitat. This phenomenon is specific to age class, and if there is no mortality amongst adult animals, most yearlings emigrate to find new forest area[13]. Thus, in order to develop an intensive harvest policy for roe deer population, knowledge of the number of animals which can be supported by the habitat (that is, social carrying capacity) is essential to avoid undesirable population losses through emigration. During 1970–75, an intensive team research study was carried out in various regions throughout Poland[6]. Deer food resources were estimated by the harvest plot method[3], and winter population densities were precisely determined by drive census techniques[11]. Based on these data, several study areas were selected in which hunting and natural mortality were very low, and where it was known that most juvenile animals emigrated each spring. We show here that summer food is a major factor limiting roe deer population size.

Census data included the proportion of fawns in the population. Amongst adults, I assumed a constant proportion of 2.01 females per male as determined by Strandgaard[13]. Adding the number of adult males and females killed by hunters, it was possible to determine the density of resident bucks (*RB*) and resident does (*RD*) in various forest types. These values were plotted next on log–log scale, against the summer food supply (*SF*), that is, deciduous browse and dicotyledonous ground flora production, because such components constitute basic summer diet of roe deer[12] (Fig. 1).

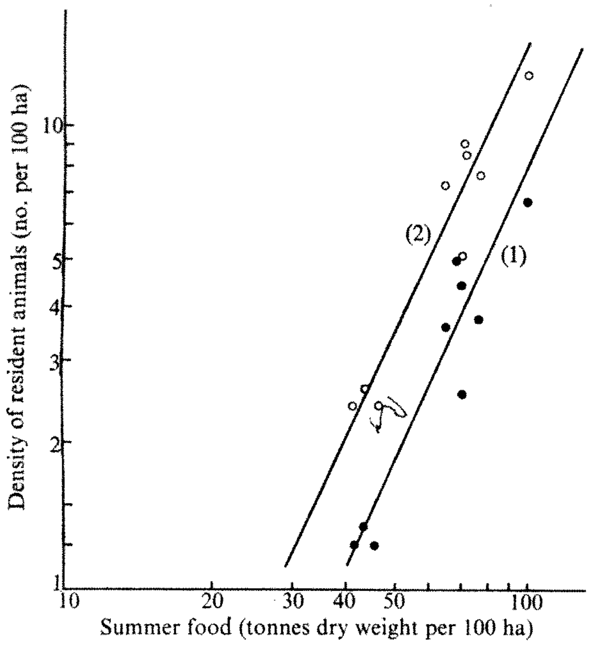

Fig. 1 Influence of summer food supply on the density of resident bucks and does. Based on studies of roe deer in Poland, 1970–75. Curve (1), $Y = 0.00058\ X^{2.06}$ (bucks). Curve (2) $Y = 0.00114\ X^{2.06}$ (does). $r = +0.93$.

Regression analysis was used to determine the relationship between the $\log_{10}$ of the density of bucks and the $\log_{10}$ of the total biomass of available summer forage (metric tons per 100 ha) for various localities. The correlation was very high ($R = 0.93$, $P < 0.05$) and is described by the formula

$$RB = 0.00058\ SF^{2.06} \tag{1}$$

Since the proportion of females is assumed above to be constant in the population, the correlation is also +0.93 and the equation determined by least square regression is

$$RD = 0.0014\ SF^{2.06} \tag{2}$$

These findings suggest that food resources are an important factor determining the number of resident bucks and does during summer season. This means that animals living in the forest with high availability of summer food, occupy smaller territory size than those inhabiting forest with poor summer food availability. Thus, territory size (TER) or home range (HR) area determines the number of resident animals per unit area; that is, the social carrying capacity of habitat, and this value may be defined by the equation

$$SC = \frac{1}{TER} + \frac{1}{HR} \tag{3}$$

This idea is important because in roe deer the summer availability determines territory or home range size, which then dictates the social carrying capacity of the habitat[13]. This is in contrast to the often held idea that the density of animals influence the territory size.

The territory size is also correlated with the age of roe deer. Using Strandgaard's data on the age of bucks and their territory size, the next relationship was determined[13]

$$Y = 11.02\ age^{0.616} \tag{4}$$

Using equation (1) and (2), and assuming the same exponent of the age of does in equation (4) to determine their home range, the territory or home range size may be expressed as function of both summer food supply and age of animal

$$TER\ (\text{ha}) = 72118.2\ age^{0.616}\ SF^{-2.06} \tag{5}$$

$$HR\ (\text{ha}) = 36632.6\ age^{0.616}\ SF^{-2.06} \tag{6}$$

Table 1 contains comparisons on summer and winter food resources for roe deer in seven common forest types in Europe[2]. Knowing total winter food consumption by a roe deer (56.3 kg dry weight; ref. 14), and using equations (3), (5) and (7), the summer (social) and winter (trophic) carrying capacities of these habitats were calculated.

If winter snow depth did not exceed 15 cm (ref. 2), the determining factor in roe deer population density is the summer carrying capacity, expressed by variation in territory size. Except the alder forest and possibly, the fresh deciduous forest type (fresh referring to mesic soil conditions), the winter carrying capacity has no effect on the density of roe deer populations. If one season reproduction results in a doubling of the population size, the winter forage can potentially limit the density in alder and fresh deciduous forest (see Table 1).

As a consequence of territoriality, roe deer possess a density-independent reproductive rate. There was a positive correlation between population density and the average number of corpora lutea per female (Table 2), but this correlation is not statistically

Table 2 Roe deer population density and average number of corpora lutea per adult female in different parts of Europe

Population density (Animals per 100 hectare) (X)	Corpora lutea per adult female (Y)	Country
13.0	2.00	Denmark (data from ref. 8)
13.3	1.85	Poland (ref. 4)
13.4	1.89	England (ref. 10)
14.9	2.18	England (ref. 10)
28.6	1.90	Poland*
56.0	2.40	Denmark (ref. 13)
63.0	1.90	Denmark (ref. 13)
63.0	2.00	Denmark (ref. 1)

$Y = 1.95 + 0.0022X$; $R = +0.27$, $P > 0.05$; corpora lutea maximum : minimum = 1.3.

The data are based on studies in Poland in 1970–75.

significant ($R = +0.27$, $P > 0.05$). It is well known that non-territorial populations of white-tailed deer (*Odocoileus virginianus*) and mule deer (*Odocoileus hemionus*) show a significant negative correlation between population density and reproductive rate. The average number of corpora lutea per female decreases as mule deer population increases ($R = -0.98$ (ref. 7)). Also, the same strong negative correlation was shown for white-tailed deer, regarding ova ($R = 0.92$) and embryos ($R = 0.90$) produced per female[7]. The ratio of maximum/minimum value of corpora lutea per female (a measure of variability) was recorded as 1.9 for mule deer[9] and 3.1 for white-tailed deer[5], but was only 1.3 in roe deer populations (Table 2).

Such small variability of number of corpora lutea per roe deer female, and the lack of correlation between density and reproductive rate probably result from spring social regulation of the population. As the territory is established to provide an individual with an adequate food resource, each individual of the same age possesses a territory large enough to provide equal amounts of summer food. Evidence which supports this thesis is the fact that the number of corpora lutea in a fenced roe deer population dropped drastically to 1.6, while free living roe deer in the same vicinity showed 2.1 per female[8].

Although this study was initiated to facilitate the intensive management of European roe deer populations, the results presented here have clear implications for an understanding of the natural regulation of populations of large herbivores.

I thank Dr M. S. Boyce for critical reading of this manuscript.

Injury requirement for initiation of regeneration of newt limbs which have whole skin grafts

THERE are three known requirements for salamander limb regeneration—injury, nerves, and wound epidermis[1,2]. During the past few years we have examined cellular events in amputated, regenerating limbs and compared these with non-regenerating limbs after either denervation[3,4] or after whole skin grafts over the amputation surface[5]. Results of these experiments led to the formulation of an hypothesis[6] which suggests unique roles for injury, nerves, and the wound epidermis during the initiation of regeneration: injury is important to cause dedifferentiation of limb stump tissue cells, entry of these cells into G_1 of the cell cycle and DNA replication; nerves are important for one or more G_2 events and thus indirectly for mitosis; and the wound epidermis maintains these cells in the cell cycle so that significant outgrowth (blastema formation) can occur. In the present study we have examined the extent and kinds of injury necessary to initiate regeneration in newt limbs which have had skin grafts for 5 weeks and externally show no regeneration. The results suggest that non-cycling dedifferentiated cells are present in 5-week skin graft limbs which immediately begin cycling when a wound epidermis forms after re-injury.

Whole skin was grafted over the amputation surfaces of 57 adult newt (*Notophthalmus viridescens*) limb stumps immediately after amputation of the limbs through the proximal portion of the radius and ulna as previously described[5]. Newts remained anaesthetised on moist gauze for 2 h and were positioned so that pressure from the gauze enhanced healing of the graft. Five weeks after amputation and skin graft, 44 of these limbs showed no external signs of regeneration. The other limbs either regenerated normally (six cases) or regenerated at a right angle from the area of skin flap overlap (seven cases) as seen in previous experiments.

These 44 non-regenerating limbs with skin flaps were either maintained as controls without re-injury or injured by: (1) a fresh amputation 1 mm proximal to the original amputation, (2) careful removal of the entire skin flap with watchmakers' forceps in order to expose the original amputation area in its entirety, and to allow new wound epidermis to form, (3) careful removal of a third of the original amputation surface to expose an area equal to only a third of the original amputation surface, (4) 15 penetrations through the skin flap with a sharp, sterile needle to a depth of 1 mm into the stump tissue, or (5) cutting a single transverse incision across the limb stump with a sterile razor blade to a depth of 1 mm into the stump tissue. We attempted to make these incisions parallel with the plane of the skin flap but they occasionally varied by as much as 20°.

The results of these various methods of injury can be seen in Table 1.

Table 1 Regeneration responses after re-injury of non-regenerating newt limbs containing skin grafts*

Type of re-injury	Number of skin graft limbs	Regeneration Yes	No
Control: no re-injury, skin graft remains intact	6	0	6
Re-amputate 1 mm into stump	8	8	0
Remove entire graft to expose entire amputation surface	8	7	1
Remove 1/3 of graft to expose 1/3 of amputation surface	5	4	1
15 needle penetrations 1 mm into stump	8	0	8
Transverse razor incision to a depth of 1 mm	9	8	1

*Limbs with skin grafts were examined 5 week after grafting. Only those which showed no regeneration were re-injured. Limbs were observed externally for regeneration at weekly intervals for 4 week.

Of the various methods used to re-injure skin graft limbs, all elicited regeneration responses with the exception of the 15 needle penetrations (Table 1). It is important to note that control amputations, removal of the entire skin graft, and removal of $\frac{1}{3}$ of the graft, all resulted in wound epidermis formation over the amputation surface, albeit only $\frac{1}{3}$ of the area in the latter case. When $\frac{1}{3}$ of the skin graft was removed, the wound area did not increase in size. Instead, regeneration occurred from the small wound surface and a small regenerate with apparently normal morphogenesis was the result.

It is surprising that 15 needle penetrations through the skin flap did not result in regeneration. Since the needle penetrations were to a depth of 1 mm into the stump, clearly some injury of stump mesodermal tissues occurred. The 15 individual wounds either did not retain free wound epidermis or the small wound epidermis areas were

Table 2 Enhanced regeneration of skin graft limbs re-injured by transverse incision compared with control amputated limbs*

Type of re-injury	Week of observation	Stages of regeneration reached Pre-mound	Mound	Cone	Paddle	Digit
Transverse incision	1	3	6	0	0	0
Amputation	1	9	0	0	0	0
Transverse incision	2	2	3	2	2	0
Amputation	2	9	0	0	0	0
Transverse incision	3	1	1	3	3	1
Amputation	3	4	5	0	0	0
Transverse incision	4	1	0	3	4	1
Amputation	4	0	6	3	0	0

*Only 5-week skin graft limbs which showed no external signs of regeneration were used for these re-injury experiments. The transverse incision was made to a depth of 1 mm into the stump. Skin grafts were made only on left limbs at which time right limbs were not amputated. Thus at 5 weeks, right limb controls were amputated for the first time. All control limbs and eight out of nine re-injured skin graft limbs eventually completed regeneration. Newts were maintained at 21 ± 1 °C throughout the experiment.

insufficient for regeneration to occur. A complete histological study of these re-injured limbs now in progress in our laboratory should clarify this problem.

Regeneration after re-injury of skin flap limbs could conceivably require dedifferentiation of stump tissues as well as wound epidermis formation[6]. According to the cell cycle hypothesis of Tassava and Mescher[6], the wound epidermis prevents re-differentiation of dedifferentiated stump tissue cells. In skin flap limbs, Mescher[5] found dedifferentiation, DNA synthesis, and mitosis 1 week after amputation to be equal to that of control amputated limbs with wound epidermis. However, by 2 weeks these parameters decreased significantly in skin flap limbs but increased in control limbs. Tassava and Mescher[6] and Mescher[5] suggested that in the absence of the wound epidermis, cells left the cell cycle and re-differentiated. The present results indicate that complete re-differentiation of limb stump cells does not occur in skin graft limbs, at least not during the 5 weeks following grafting. Particularly significant in this regard are the results of the transverse incision re-injury (Tables 1 and 2). In these limbs, a ridge formed along the incision within 4 d of re-injury in eight out of nine cases and mound blastemas were present by 1 week. From Table 2 it can be seen that some of these regenerates reached cone and even paddle stages of regeneration by 2 weeks after re-injury and digit stages by 3 weeks. Regenerates of control amputated limbs lagged far behind (Table 2). It is important to note that even at 26 °C, control newt limbs do not reach paddle or even cone stages by 2 weeks post-amputation[7]. In the present study, regeneration stages were also reached very early after entire or $\frac{1}{2}$ skin graft removals, but accurate staging data was not obtained.

What is likely, therefore, is that a significant number of dedifferentiated cells are present in skin flap limbs which are not traversing the cell cycle and thus are not seen as mitotic figures and do not label with ^{3}H-thymidine[5]. Thus when a wound epidermis forms after re-injury, these cells immediately begin cycling and dividing. Regeneration of control limbs is therefore slower because of the time required for dedifferentiation. Our preliminary histological observations are consistent with this view. It should now be possible to determine which stage of the cell cycle these dedifferentiated cells are in and whether, after even longer post-graft times, that is 8–10 weeks, similar re-injuries will elicit regeneration. These latter experiments are particularly important since Polezhaev[8] observed no regeneration when whole skin grafts were removed from axolotl limb stumps after an 8–9 week graft period. Re-injury of newt limbs with 10-week-old skin grafts will test whether dedifferentiated cells are still present and capable of blastema formation.

The regenerates which developed after a transverse incision is made through the skin flap always formed in the plane of the incision. Since some of these incisions varied by as much as 20° from the normal dorsal ventral axis of the limb, the wound epidermis seems to have a strong directional influence on regeneration, consistent with Thornton's[7] early findings. Additional experiments further varying the axis of the incision, and removing varying areas (and shapes) of skin grafts, will provide additional insights into the role of the wound epidermis in regeneration.

The results of these experiments confirm Mescher's[5] results that cell dedifferentiation initially occurs in skin graft limbs in the complete absence of a wound epidermis but DNA synthesis and mitosis then subside without outgrowth. These cells apparently remain dedifferentiated for 5 weeks since rapid blastema development is seen after re-injury and wound epidermis formation. These findings are consistent with the views presented by Tassava and Mescher[6] that the wound epidermis is not required for dedifferentiation but that it is important to keep dedifferentiated cells moving through the cell cycle.

Bilateral interaction in olfaction

THERE has been much interest in perceptual interactions between the ears and between the eyes, but much less in those between the nostrils, or more precisely, the two sides of the olfactory system[1–4]. This report reveals that, for a wide range of supraliminal stimulation, there is considerable interaction between the two sides. The facets considered here are bilateral additivity of odour intensity, and bilateral influence of an adapting stimulus presented unilaterally.

In the experiment on bilateral additivity, 20 subjects estimated the intensity of various concentrations of *n*-butyl alcohol presented to either or both nostrils. There were six stimuli—five concentrations of odorant prepared in aqueous solution plus plain water. Samples (1 ml) were placed in small vessels designed for olfactory testing and for ready assessment of vapour phase concentration[3]. Concentrations of odorant, assessed chromatographically, varied from 0.10 to 7.60 mg l^{-1} of air in a geometrical progression. On each trial, the subject sniffed the contents of two vessels simultaneously, one placed at the right and the other at the left nostril. On the first trial, both vessels contained 0.86 mg l^{-1}. The subject was instructed to assign the number 10 to the odour magnitude produced on this trial. On subsequent trials, the subject judged various left-right and right-left combinations formed from the six concentrations, including water. Of the 36 possible combinations only one, water–water, was excluded. The subject assigned numbers proportional to odour magnitude. Thus if a particular combination smelled three times as strong as the first, the subject called it 30, and so on (method of magnitude estimation)[6]. Order of presentation was irregular. Each subject served in two sessions, identical except for order of presentation.

The results, averaged geometrically across subjects, yielded a family of psychophysical functions relating odour intensity to concentration. Isointensity contours constructed from this family offer a way to decide on the degree of bilateral interaction and to compare the results reported here with analogous results in other modalities (Fig. 1)[2,7]. The contours show the combinations of concentrations to the right and left nostrils that yielded each of several odour intensities, $\psi = 5$ to $\psi = 35$.

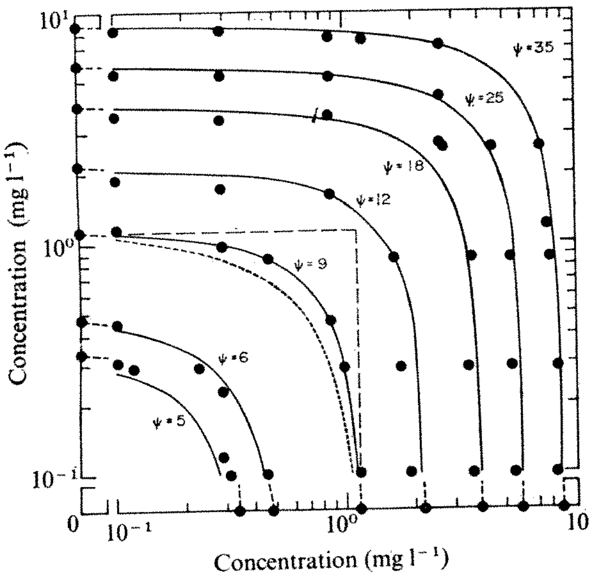

Fig. 1 Data points show the various combinations of concentrations in the right and left nostrils that led to equal perceived intensity (ψ) at various levels ranging from 5 to 35. The dashed rectilinear contour exhibits the shape that would have resulted if the perceived magnitude of a bilateral complex had equalled the magnitude of the higher concentration of the complex smelled alone. The dotted contour exhibits the shape that would have resulted if the perceived magnitude of the complex were governed by the total amount of stimulus, irrespective of how it was distributed between the nostrils. The solid contours depict the vector sum of the mass of odorant in the right and left nostrils (see equation (1)). The angle between the vectors was 60°.

The shapes of the contours showed that olfaction behaves neither like audition, where the loudness of a binaural complex falls close to the sum of the loudnesses of the monoaural components, nor like vision, where the brightness of a binocular complex characteristically falls below the brightness of the stronger monocular component[8,9]. Other straightforward possibilities merited consideration. If the perceived magnitude of the odour complex had equalled the magnitude of the higher concentration of the complex smelled alone, the contours would have a rectilinear shape (see dashed contour in Fig. 1). Alternatively, if the perceived magnitude of the complex had been governed by the total amount of stimulus, irrespective of how it was distributed between the nostrils, the contours would have the shape shown by the dotted contour. The outcome fell between these two possibilities, but resembled more closely the dotted contour, which portrays stimulus summation.

Perfect stimulus summation can be described by the equation

$$\varphi_{ab}=(\varphi_a^2+\varphi_b^2+2K\varphi_a\varphi_b)^{1/2} \qquad (1)$$

where φ_{ab} is the mass of odorant in the complex, φ_a and φ_b are the masses of the components, and where K equals 1.0. Values of K less than 1.0 reflect degrees of partial summation. To decide whether partial summation could account for the degree of bilateral additivity, the data in Fig. 1 were used to solve for K. The value obtained, 0.5, gave rise to the solid contours. These offer a good account of the results. Accordingly, the olfactory system behaved as if the effective magnitude of the stimulus in a bilateral complex were the resultant of the vector sum of the magnitudes in the components. A K of 0.5 implies a 60° angle between the vectors.

The rule of partial summation exhibited here suggests that when there is an imbalance of stimulation to the nostrils, the side receiving the stronger stimulus makes a disproportionate contribution to total intensity. This is seen in the shapes of the isointensity contours. When the magnitude of stimulation is strong on one side and weak on the other, a gradual increase in the weaker stimulus requires at first only a small compensatory decrease in the stronger in order to maintain perceived intensity constant. As the weaker stimulus approaches the magnitude of the stronger, however, the compensatory decrease becomes considerably larger, and indeed very large when the balance of stimulation shifts from one side to the other. Such behaviour could reflect inhibitory interaction between the olfactory bulbs, a process already seen electrophysiologically and one invoked to account for why the course of adaptation in rats is slowed when the anterior commissure between the bulbs is transected[10–12].

Evidence for bilateral interaction in olfactory adaptation has come also from studies of thresholds in human subjects[13–15]. Specifically, an adapting stimulus presented unilaterally serves to raise the absolute threshold for both ipsilateral and contralateral nostrils. But, the ipsilateral side shows greater and longer lasting loss of sensitivity than the contralateral side. These results implicate bulbar, or other central neural structures, in the process of adaptation[16]. It has yet to be shown, however, that the ability of an adapting stimulus to transfer its influence contralaterally occurs on the supraliminal level and with a brief monorhinic adapting stimulus that eliminates the possibility of retronasal leakage of odorant to the contralateral side. To check these possibilities, 30 subjects judged the intensity (magnitude estimation) of various concentrations of linalyl acetate presented after an adapting stimulus to the nostril ipsilateral or contralateral to the test nostril. On each trial, the subject sampled the contents of two vessels successively, but during the same continuous inhalation (4 s duration). Both adapting and test stimuli were presented on the same inhalation in order to eliminate any backflush of odorant to the contralateral posterior naris. Both nostrils were always open, thereby insuring a continuous flow of air from the anterior to the posterior nares throughout inhalation. The first vessel presented on a trial could contain just the diluent (diethyl phthalate) or linalyl acetate (0.53 mg l^{-1}, the adapting stimulus). The second could contain any of five test concentrations (0.02–1.60 mg l^{-1}). The first vessel could be presented to either the right or the left nostril, and the second could be presented ipsilaterally or contralaterally with respect to the first. The various combinations of right–left, ipsilateral–contralateral, diluent-test stimulus, adapting stimulus-test stimulus were intermingled randomly within a session. The subjects waited approximately 1 min between trials.

Figure 2 shows the psychophysical functions obtained (1)

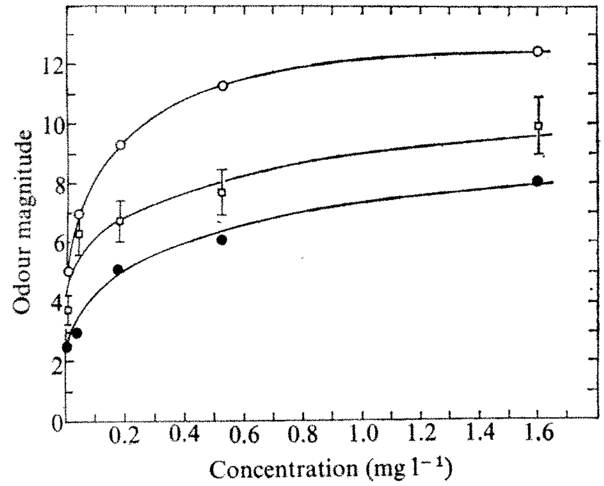

Fig. 2 Psychophysical functions for linalyl acetate obtained when test concentrations succeeded the diluent (no adaptation, ○) and when they succeeded an adapting stimulus (0.53 mg l^{-1}) on the same side (ipsilateral adaptation, ●) or on the opposite side (contralateral adaptation, □). The vertical bars represent the standard error of the difference between the results for no adaptation and contralateral adaptation (upper bars) and between the results for contralateral adaptation and ipsilateral adaptation (lower bars).

when the test stimuli succeeded the diluent, (2) when they succeeded linalyl acetate (0.53 mg l^{-1}) contralaterally and (3) when they succeeded the same concentration of linalyl acetate ipsilaterally. The functions line up in a manner consistent with bilateral interaction. Ipsilateral adaptation was characterised by a marked decrease in perceived magnitude throughout the entire range of concentrations; contralateral adaptation was characterised by a somewhat less marked, but still substantial, decrease. The difference between the two adaptation curves reflects in part the degree of peripheral neural involvement in the adaptation process. But the difference presumably reflects also any attenuation in the effectiveness of the adapting stimulus as its influence transfers contralaterally at some point in the central nervous system.

In summary, there is considerable bilateral interaction in the olfactory system. The interaction is revealed in bilateral additivity of intensity and in adaptation. The interaction seems to be independent of level of stimulation, for the same equation, based on vector addition, can describe the degree of bilateral additivity at both high and low levels of perceived intensity. The equation implies partial summation of stimulus magnitude and suggests that the nature and degree of bilateral interaction in olfaction is unique among the senses.

Bicyclic phosphorus esters increase the cyclic GMP level in rat cerebellum

4-ALKYLDERIVATIVES of 1-phospha-2,6,7-trioxabicyclo[2.2.2] octane-1-oxide (PTBO derivatives) are highly toxic organophosphates. On intraperitoneal injection to mammals they produce tonic–clonic convulsions and death within a few minutes[1,2]. Their mechanism of action is unknown, but it is different from that of other toxic phosphorus esters which act as inhibitors of cholinesterase[1]. The symptoms of poisoning by PTBO derivatives indicate an activation of the central nervous system[2]. There is evidence suggesting that the cyclic nucleotides AMP and GMP act as second messengers in central and peripheral synapses and so we have investigated the effects of PTBO compounds on the level of these nucleotides in the brain. The ethyl (EPTBO) and isopropyl (IPTBO) compounds, two of the most toxic PTBO derivatives, were used. The results show that following intraperitoneal injection of these compounds into rats, the cyclic GMP concentration is increased in cerebellum by both convulsive and subconvulsive doses, whereas the levels of the nucleotide are unchanged in cerebral cortex and subcortical tissues. The increase in cyclic GMP level in the cerebellum is thus not due to the convulsive state.

The PTBO derivatives were synthesised at FOA 4 according to the method of Wadsworth and Emmons[3]. The LD_{50} value (intraperitoneal, rats) of EPTBO was 1.1 mg kg^{-1} and that of IPTBO 0.1 mg kg^{-1} which is in agreement with values reported by others[2]. Atropine sulphate 20 mg kg^{-1} injected intraperitoneally 20 min before EPTBO did not change the toxicity of the convulsant. Diazepam 5 mg kg^{-1} administered similarly 10 min before EPTBO increased the LD_{50} value to 2.5 mg kg^{-1}.

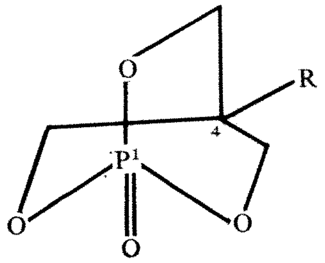

Fig. 1 4-Alkyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane-1-oxide. EPTBO: R = ethyl; IPTBO: R = isopropyl.

Cyclic nucleotides were assayed in the brains of Wistar male rats (160–300 g) injected intraperitoneally with PTBO compounds and of controls injected with 0.9% NaCl. The rats were killed by microwave irradiation (2,000 W) for 10 or 40 s for cyclic AMP and cyclic GMP respectively. Animals injected with convulsive doses (EPTBO, 1.2 mg kg^{-1}) were killed during the third tonic convulsion (about 15 min after injection). Control animals and rats given subconvulsive doses (IPTBO, 0.05 mg kg^{-1}) were killed after the same time. In some experiments diazepam (5 mg kg^{-1}) or atropine sulphate (20 or 50 mg kg^{-1}) were injected intraperitoneally before PTBO. Tissue pieces from cerebral cortex, subcortical tissues and cerebellum were homogenised at 4 °C and extracted according to Folbergrova[4]. Cyclic AMP and cyclic GMP were assayed using test kits (Radiochemical Centre, Amersham, England).

Table 1 Effects of EPTBO on the levels of cyclic AMP and cyclic GMP in different brain areas

	Cyclic AMP pmol per mg wet weight			Cyclic GMP pmol per mg wet weight		
	Control	During convulsions	*P*	Control	During convulsions	*P*
Cerebral cortex	0.32±0.05 (17)	0.34±0.11 (13)	n.s.	0.089±0.013 (6)	0.105±0.014 (6)	n.s.
Subcortical tissues	0.40±0.08 (15)	0.45±0.15 (11)	n.s.	0.137±0.013 (5)	0.187±0.032 (6)	n.s.
Cerebellum	1.29±0.21 (21)	1.74±0.27 (15)	n.s.	0.593±0.054 (8)	2.708±0.338 (8)	<0.001

Values represent the mean±s.e.m. for the number of animals given in parentheses.
P values were obtained by *t*-test; n.s. not significant.

Convulsive doses of EPTBO caused no significant differences in the levels of cyclic AMP in any of the brain areas studied compared with control animals (Table 1). The level of cyclic GMP was, however, increased almost fivefold (470% of the control values) in the cerebellum of rats with PTBO-induced convulsions whereas it was unaffected in the other brain areas studied (Table 1). A subconvulsive dose of IPTBO increased the level of cyclic GMP in cerebellum almost twofold (167% of the control values) (Table 2). Pretreatment with atropine sulphate did not significantly alter the effect of the PTBO derivatives on the cyclic GMP level. Diazepam given 10 min before the administration of the PTBO derivatives, however, blocked the increase of cyclic GMP induced by the subconvulsive dose of IPTBO and reduced the increase by the convulsive dose of EPTBO from fivefold to less than twofold (Table 2).

The elevation of cyclic GMP in the cerebellum seems not to be due to the convulsive state of the animals since a subconvulsive PTBO dose also caused an increase. The cyclic nucleotide content of postsynaptic cells in neural tissues is regulated by transmitters released from nerve terminals impinging on the cells[5,6]. Increase of cyclic GMP in the brain might be correlated to stimulation of the muscarinic cholinergic receptor (mAChR), but atropine, a well known mAChR blocker did not reduce the IPTBO-induced increase of cyclic GMP level in the cerebellum. In addition, atropine neither affected the convulsions nor decreased the toxicity of the PTBO compounds and preliminary results showed no effect of PTBO derivatives on acetylcholine release from cerebral cortex. This seems to rule out interference with muscarinic cholinergic neurotransmission.

The symptoms of PTBO poisoning are similar to those produced by bicuculline and picrotoxin, known blockers of γ-aminobutyric acid (GABA) receptors. Bowery *et al.*[7] have reported that PTBO compounds act as specific antagonists to the action of GABA. In addition we have found a slightly reduced K$^+$-induced release of ^{3}H-GABA from synaptosomes in the presence of PTBO derivatives[8]. GABA is the inhibitory transmitter released at many synapses in the cerebellum[9]. The PTBO-induced increase of cyclic GMP in the cerebellum might be caused by primary action of these agents on the inhibitory GABA mechanism. In support of this is the fact that the effects of the PTBO derivatives on the cyclic nucleotides—an increased cyclic GMP level in cerebellum and unaffected cyclic AMP—are in accordance with those described for some agents interfering with the GABA-ergic mechanism[10,11] and also that diazepam, suggested to exert a facilitory effect on GABA transmission[12], decreased both the PTBO-induced elevation of cyclic GMP and the toxicity of these compounds.

Table 2 Effects of atropine and diazepam on the PTBO-induced increase of cyclic GMP in cerebellum

Treatment	Cyclic GMP (pmol per mg wet weight)
Saline	0.593±0.054 (8)
IPTBO 0.05 mg kg^{-1}	0.989±0.048 (6)
Atropine 50 mg kg^{-1} + IPTBO	0.963 (2)
Atropine 20 mg kg^{-1} + IPTBO	0.958 (2)
Diazepam 5 mg kg^{-1} + IPTBO	0.576±0.084 (4)
EPTBO 1.2 mg kg^{-1}	2.708±0.338 (8)
Diazepam 5 mg kg^{-1} + EPTBO	1.048±0.082 (4)

Atropine 20 mg kg^{-1} and 50 mg kg^{-1} given intraperitoneally 15 and 30 min respectively before injection of IPTBO (0.05 mg kg^{-1}). Diazepam (5 mg kg^{-1}) was similarly injected 10 min before IPTBO (0.05 mg kg^{-1}) or EPTBO (1.2 mg kg^{-1}). Controls received 0.9% NaCl. Values are means ± s.e.m. for the number of animals given in parentheses.

The Purkinje cell axons of cerebellum participate in the regulation of motor activity initiated in cerebral cortex. Cyclic GMP is involved in the regulation of Purkinje cell activity and elevation of cyclic GMP in the cerebellum has been suggested to occur in those cells[9]. The cyclic GMP concentrations are suggested to be regulated by the interaction of excitatory and inhibitory transmitters[9]. Blocking of GABA action would increase the release of excitatory transmitters. The putative cerebellar transmitters glutamate and noradrenaline have both been reported to stimulate cyclic GMP synthesis in cerebellum[9,13]. The increase of cyclic GMP induced by the PTBO derivatives may be an expression of an increased release of excitatory transmitters from neurones synapsing on the Purkinje cells.

A new class of GABA agonist

COMPOUNDS which mimic the activity of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) on postsynaptic receptors are of particular pharmacological interest as possible therapeutic agents in human neurological disorders and as molecular probes with which to study different types of GABA receptors. The GABA molecule has considerable flexibility with free rotation around all three carbon–carbon bonds as indicated in Fig. 1. This conformational mobility is reduced in GABA analogues such as trans-4-aminocrotonic acid[1] and muscimol[2], which are potent GABA agonists at bicuculline-sensitive receptors on spinal neurones of the cat. The conformational mobility of such compounds can be reduced still further by incorporating the amino function in a ring structure. This has led to a new class of GABA agonist described here, based on 1,2,3,6-tetrahydropyridine-4-carboxylic acid (isoguvacine) and the related bicyclic isoxazole 4,5,6,7-tetrahydroisoxazolo[5,4-*c*]pyridin-3-ol (THIP) (Fig. 1). Isoguvacine represents a semi-rigid analogue of trans-4-aminocrotonic acid in a folded conformation. THIP, a folded analogue of muscimol, is even more rigid as the 'masked' carboxyl group (the 3-isoxazolo moiety) is fixed in the general plane of the molecule. The action of these compounds as GABA agonists provides indirect evidence that GABA interacts with bicuculline-sensitive postsynaptic receptors in the cat spinal cord in a partially extended and almost planar conformation.

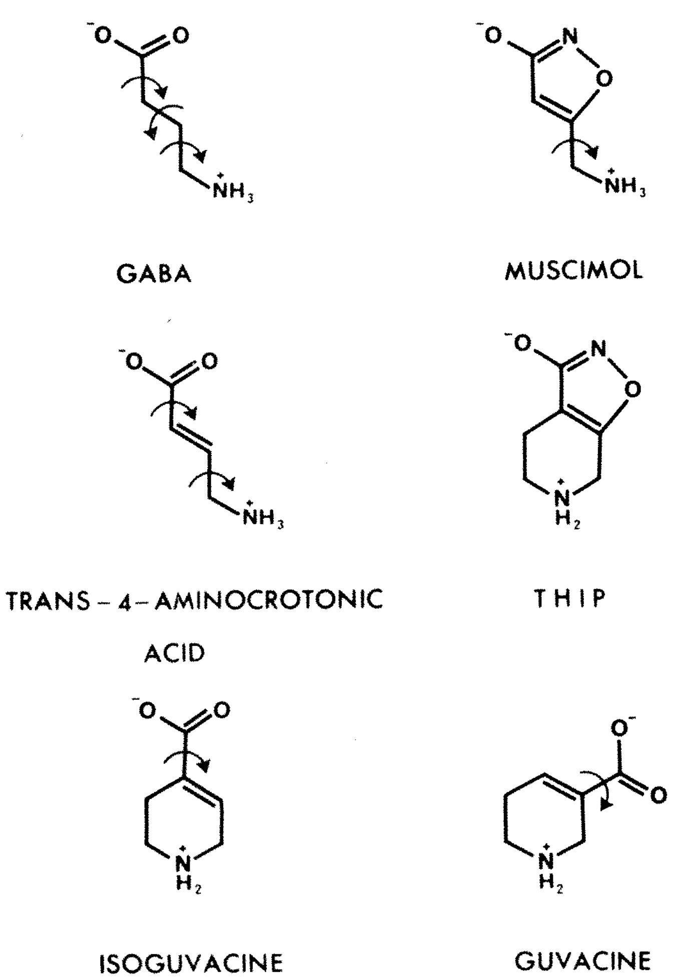

Fig 1 Conformational mobility of GABA and related compounds as illustrated by the rotational freedom around carbon–carbon single bonds marked with arrows.

Experiments were performed on lumbar dorsal horn interneurones and Renshaw cells of three cats anaesthetised with pentobarbitone sodium (35 mg per kg body weight intraperitoneally, supplemented when required). Extracellular action potentials were recorded by means of the centre barrel of seven barrel micropipettes and the compounds tested were administered electrophoretically from the outer barrels of the micropipettes[2], which contained 100 or 200 mM aqueous solutions adjusted to *p*H 3 except for bicuculline methochloride (BMC, 10 mM in 165 mM sodium chloride) and DL-homocysteate (DLH, 200 mM, *p*H 7.5). The approximate potency of any depressant action was assessed relative to that of GABA on the basis of electrophoretic currents required to produce equal and submaximal inhibitions of firing induced by DLH. *In vitro* experiments were carried out to determine the uptake of GABA (10 nM) by small slices (about 0.1 × 0.1 × 2 mm) of rat cerebral cortex[3], and the transamination of GABA catalysed by extracts of rat brain mitochondria[4]. The syntheses of the new compounds isoguvacine and THIP will be described elsewhere. Muscimol and BMC were prepared by published procedures[5,6]. All other compounds were purchased from commercial suppliers.

The depressant action of isoguvacine (tested on 10 neurones) was comparable with that previously reported for muscimol[2], and was two to four times more potent than that of THIP (eight neurones) and GABA which were approximately equipotent. The depressant action of all of these compounds was reversibly antagonised by bicuculline methochloride in conditions where the inhibitory action of glycine was unaffected (Fig. 2). The saturated analogue of isoguvacine, piperidine-4-carboxylic acid, also depressed the firing of spinal interneurones (3) with a potency similar to that of GABA, and this action was also reversibly antagonised by BMC.

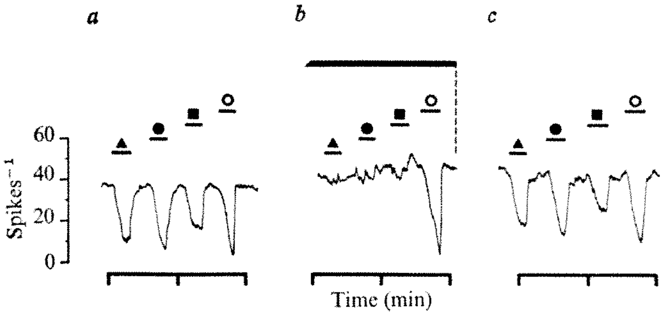

Fig 2 The effect of bicuculline methochloride (BMC) on the inhibition of the firing of a spinal interneurone by isoguvacine (35 nA; ●), THIP (60 nA; ▲), GABA (60 nA; ■), and glycine (15 nA; ○) ejected for the times indicated by the symbols and horizontal bars. The firing of the neurones was maintained with continuously ejected DL-homocysteate (DLH, 10 nA). The relative effectiveness of the inhibitory amino acids is similar to that observed in all experiments. *a*, Before; *b*, during BMC (15 nA) which was terminated at the vertical broken line; *c*, 3 min after (*b*).

As with the development of inhibitors of the neuronal uptake of GABA such as nipecotic acid[7] and guvacine[8], the present investigation arose from studies of the structure–activity relationships of isoxazoles related to muscimol. Isoguvacine and THIP were inactive at 0.5 mM as inhibitors of the neuronal uptake of GABA by slices of rat cerebral cortex, and also at 1 mM as inhibitors of the transamination of GABA catalysed by extracts of rat brain mitochondria. It is of interest to contrast isoguvacine and guvacine (Fig. 1) with respect to bicuculline-sensitive GABA receptors on spinal neurones and to transport carriers mediating the neuronal uptake of GABA in brain slices: isoguvacine is apparently a potent agonist with respect to these receptors and inactive against the carriers, whereas guvacine seems to be inactive as a GABA agonist[9] and a potent substrate-competitive inhibitor of the carriers[8]. These results are in agreement with the proposal that these particular postsynaptic receptors and transport carriers for GABA exhibit different structural specificities[10]: isoguvacine and guvacine may represent two different 'active conformations' of GABA selectively interacting with the bicuculline-sensitive postsynaptic receptors and neuronal uptake carriers respectively.

Abnormal adenine metabolism of erythrocytes in Duchenne and myotonic muscular dystrophy

Duchenne muscular dystrophy (DUD) and myotonic muscular dystrophy (MYD) are inherited as sex-linked recessive and autosomal dominant traits, respectively. Although the primary manifestation is progressive muscle weakness, multiple organ systems seem to be affected. Cardiac abnormalities and mental retardation are described in both conditions, and defects in immunoglobulins and endocrine functions have been reported in MYD[1]. The primary inherited metabolic defect is unknown, but there is evidence to suggest an abnormal sarcolemmal membrane[1]. The possibility that muscle disease, especially involving membrane dysfunction, is reflected in the erythrocytes is supported by the demonstration of defective phosphorylation in the erythrocytes of patients with DUD[2] and MYD[3]. In DUD the erythrocytes appear abnormal in the scanning electron microscope[4] and in MYD electron spin resonance reveals abnormal membrane fluidity. There are other reasons to study erythrocytes, for the direct study of muscle is hampered by the need for repeated biopsies and by atrophy and fibrous tissue, which can cause secondary biochemical changes. Furthermore, the yield of isolated sarcolemmal membranes is often small and impure. In DUD, there is a 30% reduction in muscle ATP[6] and an abnormal ATP : ADP ratio of 1.57. Whether this is a significant defect or is a result of secondary changes in the muscle has yet to be clarified. We report here that the intracellular phosphorylation of adenine nucleotides derived from adenine incorporated by the erythrocytes is abnormal in both DUD and MYD.

Ten DUD patients from 10 families, five DUD carriers (two obligate, two probable, one possible) from five families, and seven MYD patients from five families were used and compared with 16 normal subjects, eight patients with other neuromuscular diseases, and four patients with a variety of disorders. 2.5 ml of heparinised venous blood was obtained from each patient in double blind conditions and spun at slow speed (800 r.p.m. 12-inch diameter rotor) for 17 min at 20 °C. The platelet-rich-supernatant plasma (PRP) was removed and separately centrifuged at 3,000 r.p.m. for 5 min to obtain platelet-poor-plasma (PPP). The red cell fraction after removal of PRP was centrifuged at 3,000 for 5 min to pack down the cells. 0.2 ml of packed red cells drawn from the centre of the sample was mixed with 0.2 ml of their own PPP in a polyethylene tube at 37 °C in a water bath. 10 µl of U-^{14}C-adenine (1 µCi) was added and incubation continued with gentle shaking for 30 min. The tubes were cooled briefly in ice and 0.5 ml of cold 13% perchloric acid (PCA) was added. After mixing and centrifuging at 3,000 r.p.m. the clear PCA supernatant (15 µl) was chromatographed on thin-layer cellulose sheets using a solvent of formic acid–teramyl alcohol–water (10 : 15 : 5). After drying each run was cut into 1-cm strips and the radioactivity determined on a liquid scintillation spectrometer[7]. Each peak was calculated as a percentage of the total ^{14}C-nucleotide pool formed during the incubation period and the profile of peaks run was summarised as a ratio R=(ATP+ADP)/AMP which describes the relative proportions of high-and-low energy compounds. All assays were performed within 2 h on fresh erythrocytes without freezing or storage.

The results on red cells suspended in their own plasma showed significant difference in the ratio of ATP+ADP to AMP of the patients, when compared with normals and disease control (Table 1). The mean ratio (R) for the normal subjects and disease controls were 9.6±4.1 and 8.7±4.6. MYD patients showed the greatest reduction in their ratio, with a mean of 2.9±1.8 but there was also a significant reduction in DUD (4.9±2.9). Thin-layer chromotography usually demonstrated a reduction in the proportions of both ATP ADP and an increase in AMP production. ^{14}C-adenine was present in all cases in excess so that it was not rate limiting, but the data suggested that adenine uptake was reduced in the DUD and MYD patients.

ATP exerts a protective effect on cell membrane integrity[8]. Thus any condition which leads to a decreased proportion of intracellular ATP is likely to result in leakage of enzymes and other proteins. As well as acting as a reserve of energy, ATP may have a direct effect in maintaining the integrity of the cell membrane, since it is concerned in the biosynthesis of phosphatidic acids, intermediates in the synthesis of phospholipids in membranes[9].

Our findings are indicative of appreciable metabolic disturbances in red blood cells of MyD and DuD, which are apparently insufficient to produce gross physiological

Table 1 Mean per cent of ^{14}C-adenine nucleotide pool in RBCs

dysfunction and therefore may be a useful partial model for the further study of these genetic disorders.

The concept of failure to maintain a normal profile of adenine nucleotides may be an important factor in the membrane defect in Duchenne and myotonic dystrophy and needs further investigation.

Amino acid sequence similarities between amyloid P component C1t and CRP

THE P component is a normal 9.5 S serum α1 glycoprotein composed of subunits that is found as a minor constituent of all types of amyloid deposits[1,2]. Painter *et al.*[3] have described a 9.5 S α1 glycoprotein, C1t, composed of ten 23,000 molecular weight (MW) subunits, which may have an important role in the regulation of complement C1 function. Ultrastructural and immunological studies showed a striking resemblance between P and C1t (refs 3, 4). CRP is an acute phase reactant, present in many species which can interact with pneumococcal C-polysaccharide, choline phosphatides and various polycations to activate the complement cascade[5,6]. It is composed of a 23,000 MW subunit non-covalently linked as a pentamer[7]. A clear-cut structural relationship between C1t and CRP has been demonstrated by comparing amino terminal sequences[7]. Since all three molecules—P, C1t and CRP—have a similar ultrastructure, namely, a cyclic pentamer or a decameric double, the term 'pentraxins' has been proposed by Osmand *et al.* for this group of molecules[7]. We report here the characterisation and the amino terminal sequence of human P component. The P component is identical to C1t except for the absence of the first residue (His), thus providing additional evidence for a close evolutionary relationship for P, C1t and CRP.

P component was isolated by saline extraction, Sephadex, diethylaminoethyl and cellulose chromatography, according to the method of Skinner *et al.*[2], from the liver of a patient (WIL) with secondary amyloidosis. By sodium dodecylsulphate–polyacrylyamide gel electrophoresis, the material consisted of a single 23,000 MW component which had a tendency to aggregate in reducing conditions. Figure 1 compares the amino acid sequence of the first 27 residues with those of C1t (ref. 7), three partially sequenced P components[2,4], and CRP (ref. 7). When compared to C1t, our preparation is one residue shorter at the amino terminal. The amino terminal residue could not be identified but the remaining 25 residues were identical. Position 19 is tentative since tyrosine was identified by thin layer chromatography and histidine by amino acid analysis after back hydrolysis. Differences between our P component and those reported previously[2,4] may be due to individual differences between different preparations or perhaps, in several instances, due to carry-over or other technical problems in residues that are difficult to identify. A closer similarity between C1t and P than between these molecules and CRP is suggested by the finding that both anti-P and anti-C1t antibodies gave a reaction of identity with P, as shown previously[4], while there was no antigenic relationship between P and CRP. Our anti-P antibody did not react with various preparations of CRP and four antibodies to native and denatured CRP did not react with P (WIL).

These results raise the possibility that there is a series of structurally closely related proteins which may have an important role in regulating and modulating certain immunological and inflammatory reactions[7]. Interestingly, our tissue-derived P component seems to lack the first residue, perhaps as a result of proteolytic cleavage. The structural and antigenic identity observed between C1t and P suggests a closer relationship between them than with CRP. But we do not yet have sufficient data to conclude that they are indentical. Study of the interaction of P with antigen antibody complexes, complement components

Fig. 1 The amino terminal sequence of human P compared with previously published sequences of P (refs 2, 4), C1t (ref 7) and a cyanogen bromide fragment of CRP (ref. 7). Numbering and homology are based on the sequence of C1t. Amino acid sequence analysis was performed by using a Beckman 890C sequencer and the Beckman DMAA peptide program. Identification of amino acids was done by three methods: (1) gas–liquid chromatography on a 762 0A Hewlett-Packard gas chromatograph[8]; (2) thin-layer chromatography (TLC) of PTH-amino acids on 5 × 5-cm polyacrylamide plates in two dimensions[9]; (3) amino acid analysis using HI for hydrolysis[10]. Sequence identities are indicated by —. Unidentified residues by ( ). Residue 19 yielded tyrosine on TLC and histidine on back hydrolysis. In our conditions of amino acid analysis, PTH tyrosine is often lost and may elute with histidine.

and certain other substances (Y.L., I. Gigli, B.F. and E.C.F., in preparation), as well as further amino acid sequence studies will allow a more precise structural and functional comparison with C1t.

An anterior pituitary factor stimulates thymidine incorporation in isolated thymocytes

A POSSIBLE tropic role of pituitary on thymus has been suggested by several studies. Hypophysectomy causes an atrophy of the gland[1-4] and thymus is poorly developed in Snellbagg genetically dwarf mice with hypopituitary function[5]. A diminution of thymus size and a reduction in immunological responses to T cell-dependent antigens is also seen after administration of anti-hypophyseal serum[6]. The pituitary may contain several active principles affecting directly or indirectly the thymus functions. Of these, growth hormone has been shown to have a promoting effect on metabolic activities of the thymus and on immune responses involving the participation of thymus-derived T cells[4,7,8]. Thyrotropin, via the thyroid hormones, also exercises a thymotropic action[9]. ACTH, via corticosteroids, causes the transient diminution of the gland[10]. We report here the presence in pituitaries of a previously unknown small molecular weight peptide(s) which stimulates markedly the incorporation of tritiated thymidine into DNA in isolated thymocytes.

Figure 1 shows that the addition of the anterior pituitary extract (APE) to the isolated thymocytes resulted in a notable stimulation of the incorporation of ^{3}H-thymidine into cold trichloroacetic acid (TCA)-precipitable pellet. A stimulation with APE was consistently obtained but the extent varied from preparation to preparation of APE and thymocytes. Thymocytes from young rodents gave a better response than those from aged animals. Table 1 shows the order of variation in stimulation by APE of ^{3}H-thymidine incorporation in thymocytes obtained from six different animals. Variance analysis of the data indicates that between-animal variations are significantly more marked than between tube variations (variance ratio $F = 29.9$, 8.5 times more than required for significance at 1% level). These variations probably arise due to different internal environments to which the thymocytes are exposed before the animals were killed. The effect of APE is highly significant ($F = 1163.5$) and is much more than the animal-to-animal variations (variance ratio 159.2 times higher than that required for 1% significance level).

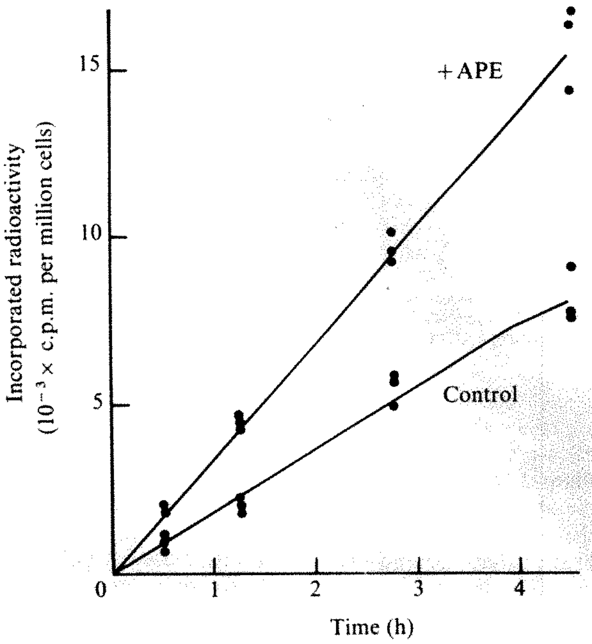

Fig. 1 Effect of anterior pituitary extract (APE) on ^{3}H-thymidine incorporation in isolated thymocytes. APE was the 2000*g* supernatant of rat anterior pituitary homogenates in GS medium (glucose salt medium, containing 120 mM NaCl, 5 mM KCl, 5 mM Na$_2$HPO$_4$, 1 mM MgSO$_4$, 0.8 mM CaCl$_2$, 5.5 mM glucose and 5 mM Tris-HCl buffer, *p*H 7.2). Rat thymocytes (15×10^6 ml^{-1}), were incubated in GS medium at 37 °C with ^{3}H-thymidine (0.5 μCi ml^{-1}, 2 μM) ± APE (added to a final concentration of 0.25 anterior pituitary equivalents per ml of final incubation medium). At different time intervals, the incorporation reaction was stopped by chilling and by adding excess (0.5 mM) of non-radioactive thymidine to the incubation tubes. Cells were centrifuged (600*g* for 10 min), washed with fresh GS medium, followed by two washings with cold 10% trichloroacetic acid and two with methanol. The pellet was dried and dissolved in 0.1 ml Soluene, transferred to the scintillation vials with a toluene-based scintillation mixture and the incorporated radioactivity measured in a Packard liquid scintillation spectrometer.

The incorporated radioactivity was sensitive to DNase but not to RNase treatment. Viability of cells was measured at each time point by Trypan blue exclusion and no significant difference was noted in control and APE added tubes.

To identify the pituitary hormones that may be responsible for this action of APE, rat growth hormones (NIAMD-rat GHB1), luteinising hormone (NIH-LH-S 17), follicle-stimulating hormone (NIH-FSH-S 9), thyrotropin (NIH-TSH-B 4), prolactin (NIH-P-B 3) and ACTH (pork ACTH, Chemical Lab. Friderikberg, Denmark) were tested singly and in combination. Two hormone combinations were prepared: in mixture A the hormones were present at their approximate physiological level in pituitary and in mixture B, at five times higher concentration. These hormones caused a marginal increase in thymidine incorportion, but the effect was not comparable with that obtained with APE (Table 2). The active principle in the extract thus seems to be different from these hormones.

The factor was dialysable and heat stable and was distinct from LH and TSH releasing hormones. The activity was not present in hypothalamic extracts or in posterior pituitary and cerebral cortex extracts. Cyclic nucleotides and inorganic ions did not give parallel stimulation of this metabolic activity in isolated thymocytes. The stimulatory effect was not due to the possible supply of essential

Table 1 Effect of anterior pituitary extract (APE) on ^{3}H-thymidine incorporation in thymocytes from six young rats

Rat	Body weight (g) and sex	Cell density in assay medium (million per ml)	Incorporated radioactivity c.p.m. per million cells ± s.e.m. Control	+ APE	% Of control
1	94.5 (F)	4.40	2652±133 (3)	7086±174 (4)	266.5
2	77.6 (F)	4.52	1832± 55 (4)	4483±210 (4)	244.7
3	74.3 (M)	5.12	2189± 28 (4)	5451±169 (4)	249.0
4	88.7 (F)	3.88	2964± 80 (4)	6553± 84 (4)	221.1
5	69.1 (F)	4.80	2824± 64 (4)	6041±295 (4)	213.9
6	44.1 (M)	1.76	2184± 42 (4)	6696±195 (4)	306.6

Thymocytes prepared separately from six young rats were incubated at 37 °C for 2 h ± APE (0.8 anterior pituitary equivalent per ml) in GS medium containing 1 μCi ml^{-1} ^{3}H-thymidine (1 μM). Values in parenthesis are the number of replicates for each preparation of cells.

nutrients by the APE, and was also obtained when experiments were performed in tissue culture media RPMI and Medium 199.

The stimulatory activity of the APE on thymocytes was sensitive to hog intestinal peptidase (from Sigma, containing general proteolytic and aminopeptidase activity) but not to DNase, RNase and trypsin. The factor may therefore be a peptide. Its molecular weight (MW) is 500, and the isoelectric *p*H 7.9. Purified preparations of the factor do not show significant ultraviolet absorption above 230 nm. These properties indicate that this factor is distinct from other factors of pituitary origin described in recent years by other investigators. Fibroblast growth factor from bovine pituitaries[12] has a MW of 13,300. Chondrocyte mitogenic factor[13] is a heat-labile entity and was detected as a contaminant in anterior pituitary hormone preparations. The factor influencing the ovarian cells in culture[14] is a non-dialysable protein. Lipotropins[15] are big polypeptides (6,000 and 11,400 molecular weight). A hypophysial factor influencing the steroid metabolism in rat hepatoma cell lines[16] is a high molecular weight entity and in contrast to present case, is present only in female pituitaries. Pituitary endorphins[17] are polypeptides of 3,000–3,500 MW.

The action of APE on uptake and incorporation of thymidine seems to be tissue specific. Thymocytes show maximal stimulation but lymphoid cells derived from spleen and lymph nodes are also stimulated, though to a lesser extent. APE did not have stimulatory effect on thymidine incorporation in tissue slices from liver, kidney, heart and diaphragm.

The biological role of this factor(s) is not fully known. It may influence the proliferation of cells within thymus. Mouse embryonic thymus cultures in media containing this factor show higher cellularity than parallel control cultures.

Thymus is an organ characterised by a high rate of cellular proliferation, which is independent of the antigenic stimulus[11], and not much is known on the factors regulating the metabolic activities and the rate of cell proliferation in this tissue. The size of this gland shrinks with hypophysectomy[1–4]. The gland is also atrophied in states of hypopituitary function[5]. It is thus conceivable that pituitary exercises an effect on lymphoid cell proliferation in thymus. The presence of a factor exerting a marked influence on DNA synthesis in thymocytes is thus of interest.

Table 2 Effect of anterior pituitary hormones and anterior pituitary extract on the incorporation of thymidine into isolated thymocytes

Addition	Incorporated radioactivity c.p.m. per million cells Mean ± s.e.m.	% Of control
None	429±31 (4)	100.0±7.2
Hormone mixture (A)	536±42 (6)	124.9±9.8
Hormone mixture (B)	584±57 (5)	136.1±13.3
Anterior pituitary extract (APE)	1567±95 (5)	365.3±22.1

Five million rat thymocytes in 1 ml GS medium, were incubated with tritiated thymidine (0.5 μCi ml^{-1}, 2 μM) with or without hormones/APE at 37 °C for 2 h in a Dubnoff metabolic shaker. Hormone mixture (A) contained at final concentration, 25 μg of GH, 20 μg each of TSH, FSH, LH and prolactins and 10 μg of ACTH per ml of incubation medium. Mixture (B) had five times the concentration of these hormones. APE was added at one rat anterior pituitary equivlaent per ml of final incubation medium. Figures in parenthesis give the number of replicates in each case.

Propranolol increases binding of thyrotropin to thyroid membranes

β-ADRENERGIC antagonists such as propranolol possess two pharmacologically relevant properties—β-adrenergic blockade is observed at relatively low concentrations, whilst at higher concentrations they are effective membrane stabilising agents[1,2]. The latter property which, unlike β-adrenergic antagonism is non-stereospecific, is also described as local anaesthetic or quinidine like activity and it possibly accounts at least in part, for the anti-arrhythmic properties of propranolol—local anaesthetics and quinidine also showing anti-arrhythmic activity[3–5]. A wide variety of effects have been associated with local anaesthetic activity[1], but as yet there is no unifying explanation of the mechanism of action. We have investigated the effect of propranolol, acting in its capacity as a local anaesthetic, on a hormone receptor adenylate cyclase system which might be expected to be sensitive to membrane perturbation by local anaesthetics, and reported inhibition of thyrotropin (TSH) stimulation of adenylate cyclase in thyroid plasma membranes[6]. We present here a study of the consequence of local anaesthetic activity on binding of the hormone to membrane-associated receptors, and in this respect contrast the local anaesthetic activity of propranolol with that of local anaesthetics such as xylocaine or procaine.

^{125}I-TSH binds to plasma membranes derived from the thyroid in a reversible and specific manner, consistent with binding of the hormone to its physiologically relevant receptor linked to adenylate cyclase (see ref. 7 for review). Using experimental conditions previously described[8], we confirmed that ^{125}I-TSH bound to membranes prepared from the human thyroid can be significantly displaced by additions of the order of 25 μU of unlabelled TSH, and also by immunoglobulins derived from thyrotoxic sera[9], and have observed that relatively high doses of insulin, growth hormone, luteinising hormone and follicle-stimulating hormone produced no significant inhibition. As shown in Fig. 1, addition of D-propranolol (10^{-3} M) inhibited TSH stimulation of adenylate cyclase in human thyroid membrane preparations, but produced a highly significant increase in binding of the hormone to the membranes. The high concentrations of propranolol required to increase binding (10^{-3} M) and the equipotency of the D and L isomers of propranolol (not shown) together with the observation that quinidine (10^{-3} M) caused a similar increase, suggested that, as was previously reported for the inhibition of adenylate cyclase[6], the increased binding was attributable to the local anaesthetic properties of propranolol.

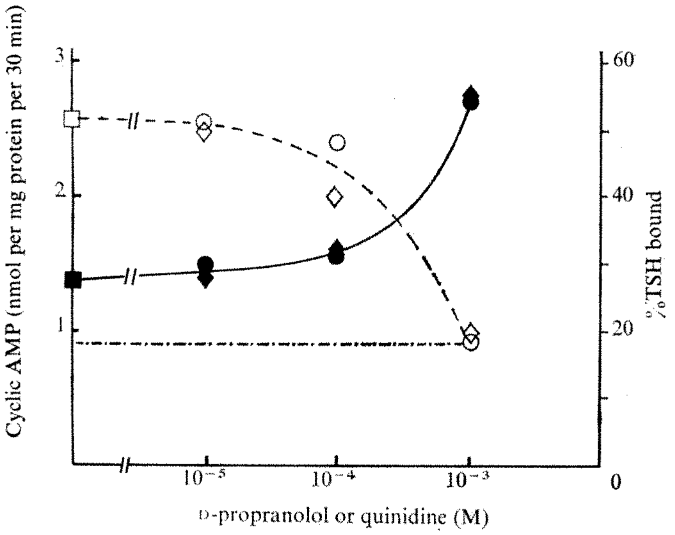

Fig. 1 The effect of propranolol and quinidine on TSH binding and stimulation of adenylate cyclase in human thyroid membranes. Membrane preparation and receptor purification of bovine ^{125}I-TSH were as described by Smith and Hall[8]. Binding was studied by incubating the membranes (50 μl at 2 mg protein per ml) with 200 μl iodinated bovine TSH (10,000 c.p.m. ml^{-1}) in the presence or absence of propranolol or quinidine, added as 50 μl of assay buffer (10 mM Tris-HCl, *p*H 7.5, 50 mM NaCl, 0.1% bovine serum albumin) with or without propranolol or quinidine (quinidine sulphate, Sigma). The incubation was terminated after 1 h at 37 °C by the addition of 1 ml of ice-cold assay buffer, the membranes then being separated by centrifugation (25,000*g*, 30 min at 4 °C), removal of the supernatant, and bound TSH determined by counting the membrane pellet. Stimulation of adenylate cyclase in the human thyroid membranes by bovine TSH (Armour, 1 U mg^{-1}) was as described before[6]. TSH (100 mU ml^{-1}) was added to membranes (2 mg protein per ml) in the presence of 2.5 mM ATP, 5mM Mg^{2+}, 10 mM theophylline, 10 mM creatine phosphate and 20 μg crystalline rabbit muscle creatine kinase, and the incubation terminated after 30 min at 37 °C. Cyclic adenosine 3′,5′-monophosphate was assayed by the method of Broan *et al.*[10]. TSH binding (means of duplicate determinations): ■, binding in absence of propranolol or quinidine; ●, binding in the presence of propranolol; ◆, binding in the presence of quinidine. TSH stimulation of adenylate cyclase (means of quadruplicate determinations): - - - - - -, basal, unaffected by propranolol or quinidine (10^{-3} M and less); □, TSH stimulated activity in absence of propranolol or quinidine; ○, TSH stimulated activity in presence of propranolol; ◇, TSH stimulated activity in presence of quinidine.

Table 1 The effect of β-adrenergic antagonists on binding of ^{125}I-TSH to human thyroid plasma membranes

Additions	% of ^{125}I-TSH bound (less nonspecific)
Experiment 1	
None	28.9±0.6
D-propranolol (10^{-3}M)	43.7±1.0
Oxprenolol (10^{-3}M)	32.5±0.4
Sotalol (10^{-3}M)	30.3±2.9
Alprenolol (10^{-3}M)	42.2±0.1
Experiment 2	
None	16.5±0.8
DL-propranolol (10^{-3}M)	57.4±2.2

None	22.8±1.4
D-propranolol (10^{-3}M)	53.5±0.7
Oxprenolol (10^{-4}M)	22.6±0.3
(10^{-3}M)	23.2±1.0
(5×10^{-3}M)	33.9±0.7
(10^{-2}M)	42.6±0.2
Practolol (10^{-5}M)	23.2±0.7
(10^{-4}M)	22.9±0.01
(10^{-3}M)	21.9±0.1

Experimental conditions used were as described in legend to Fig. 1. All drugs were in the form of the hydrochlorides, except metoprolol tartrate.

We investigated this further by comparing the effects of analogues of propranolol, all of which were β-adrenergic antagonists, but which varied in potency as local anaesthetics. When each drug was added to give a final concentration of 10^{-3} M, increased binding was observed in the presence of alprenolol, which possessed local anaesthetic potency comparable with propranolol and quinidine[11,12], but not following the addition of metoprolol, oxprenolol, sotalol or practolol, reported to exert comparatively little local anaesthetic activity[12,13] (Table 1). But, increasing oxprenolol concentrations to 10^{-2} M resulted in an increased binding which is consistent with its intermediate potency as a local anaesthetic[12].

Table 2 Effect of predicaine, carbocaine, xylocaine, procaine, and chlorpromazine compared with that of propranolol and quinidine on ^{125}I-TSH binding to human thyroid plasma membranes

(10^{-4}M)	33.1±0.5
(10^{-3}M)	12.9±2.2

Experimental conditions were as described in the legend to Fig. 1.

Although increased binding of TSH apparently correlated with the local anaesthetic activity of β-adrenergic antagonists and quinidine, it is interesting that no increase was observed following the addition of the local anaesthetics xylocaine, predicaine, carbocaine and procaine. Detailed investigations, adding concentrations of xylocaine ranging from 10^{-7} to 10^{-1} M caused no increase in binding (not shown) and at concentrations of the order of 10^{-1} M, binding was reduced with xylocaine and the other local anaesthetics (Table 2). Another membrane stabilising agent, chlorpromazine, was found to increase binding when present at 10^{-4} M, although no such effect was reported by Moore and Wolff[14].

Scatchard analysis of the increased binding due to the presence of D-propranolol (10^{-3} M), suggests that it is due to an increase in apparent affinity of the hormone for the receptor, rather than an increase in the number of receptors (Fig. 2). Explaining the nonlinear plots as due to the presence of a high- and low-affinity binding sites, they may be interpreted to indicate an increase in affinity of the high-affinity site from 2.5×10^9 l mol^{-1} to 8×10^9 l mol^{-1} in the presence of propranolol.

The detailed mechanism by which propranolol might increase the affinity of the receptor for TSH is unknown, but evidence from several investigations suggests that it may be primarily due to changes in the hydrophobic lipid environment of the membrane-associated receptors. A correlation between increased local anaesthetic potencies of β-adrenergic antagonists and an increase in their hydrophobic nature has been recognised[12], and increased binding of TSH to thyroid membranes has also been reported in the presence of filipin and following membrane treatment with phospholipase A (ref. 14). Moreover, a sharp increase in binding of TSH observed at temperatures of 30 °C and above has been associated with increased fluidity of membrane lipids, as characterised by motional characteristics of three membrane bound fluorescent probes[15]. It is well recognised that TSH stimulation of adenylate cyclase in membranes is sensitive to the presence of phospholipids[16] and the observation that local anaesthetics interact specifically with anionic phospholipids[17] might account for the effect of D-propranolol on the TSH stimulation[6,18].

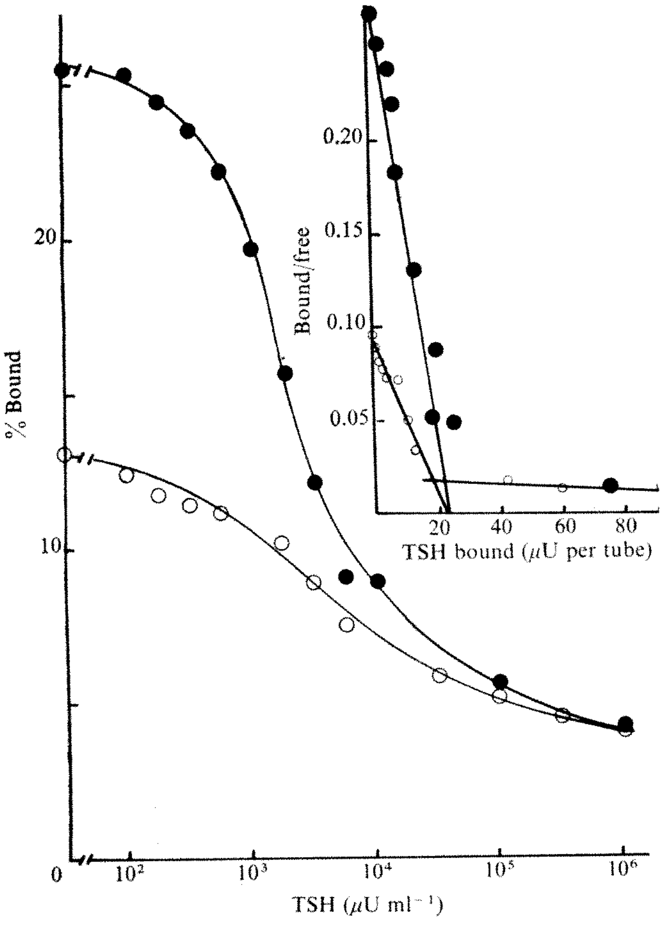

Fig. 2 The effect of propranolol on the binding of bovine ^{125}I-TSH to human thyroid membranes in the presence of additional unlabelled bovine TSH. Experimental conditions were as described in the legend to Fig. 1, and unlabelled TSH (Armour, 1 U mg^{-1}) was added at the concentrations shown. The Scatchard plot of these results is shown inset. ○, In the absence of 10^{-3} M D-propranolol; ● in the presence of 10^{-3} M D-propranolol.

Local anaesthetic activity of β-adrenergic antagonists might also be expected to be effected by local anaesthetics such as xylocaine, and it is significant that despite the correlation between the local-anaesthetic properties of β-adrenergic antagonists and their ability to increase binding, a similar effect was not observed with the local anaesthetics of either the amide or ester type included in this study.

We are grateful to the Wellcome Trust for financial support. We also acknowledge the generous gifts of practolol, and the optical isomers of propranolol from ICI, alprenolol from Hassle, oxprenolol and metoprolol from CIBA-Geigy, Sotalol from Mead Johnson and predicaine, xylocaine, carbocaine and procaine from Pharmaceutical Manufacturing Co. We thank Dr J. G. Pierce for highly purified bovine TSH.

Polypeptides similar to the α and β subunits of tubulin are exposed on the neuronal surface

THE finding by Borisy and Taylor[1] that nervous tissue was the source of large amounts of soluble tubulin, the subunit protein of microtubules, has greatly facilitated the biochemical study of microtubular structure. From 10% to 20% of the total protein of developing brain is in the form of soluble tubulin[2,3] and most studies have focused on this form of the protein. In 1970, however, Feit and Barondes demonstrated a large amount of colchicine binding activity, a term which has become associated with the presence of tubulin, in particulate fractions of brain[4]—fractions expected to be free of microtubule-derived tubulin. Recent studies indicate that polypeptides with the same size and drug-binding properties as soluble tubulin are present in synaptosomal plasma membranes[5–7]. These studies suggest a membrane-associated form of the protein which is insoluble in non-chaotropic buffers. I here report experiments which provide additional evidence for membrane-associated tubulin-like proteins and also suggest that a portion of this polypeptide(s) may be exposed on the external surface of the cell.

Superior cervical ganglia from perinatal rats were separated into three to four pieces and cultured on collagen-coated dishes. The general properties of this nerve cell in culture have been reviewed[8,9]. These explants were treated with a combination of antimitotic drugs, in a regimen modified from that used on dorsal root ganglion by Wood and Bunge[10], in order to suppress all cellular growth except that of the neurones. The result of three weeks' growth of four explants in one culture is shown in Fig. 1. The neurones within the explant produce copious neurites, up to 5 mm in length and the dish contains essentially no non-neuronal cells. Such cultures were used to isolate samples of neurites free of their cell bodies and of non-neuronal cells by simple excision and removal of the explant regions from the dish, with subsequent harvest of the extensive neurite outgrowth.

If such explants are given radioactively labelled amino acids in their culture medium, it is possible to demonstrate, by autoradiographic analysis of SDS–polyacrylamide gels of neuronal polypeptides, that the synthesis of tubulin and actin account for as much as one-third of total protein synthesis (ref. 11 and my own data, not shown). Furthermore, since the neurites are metabolically dependent on the cell somata for polypeptides needed in their growth and maintenance, it is possible to study the transport of protein from the somata into the neurites. In pulse-chase experiments of this type, polypeptides co-migrating with tubulin are among the most prominent seen by fluorography (Fig. 2).

When a similar experiment is carried out using fucose as a precursor, polypeptides co-migrating with the tubulin subunits are again heavily labelled (Fig. 3). Comparison of soluble and particulate fractions from these neurites reveals that little or no fucose-derived radioactivity is associated with the soluble tubulin but that the particulate fraction contains heavily labelled polypeptides co-migrating with tubulin.

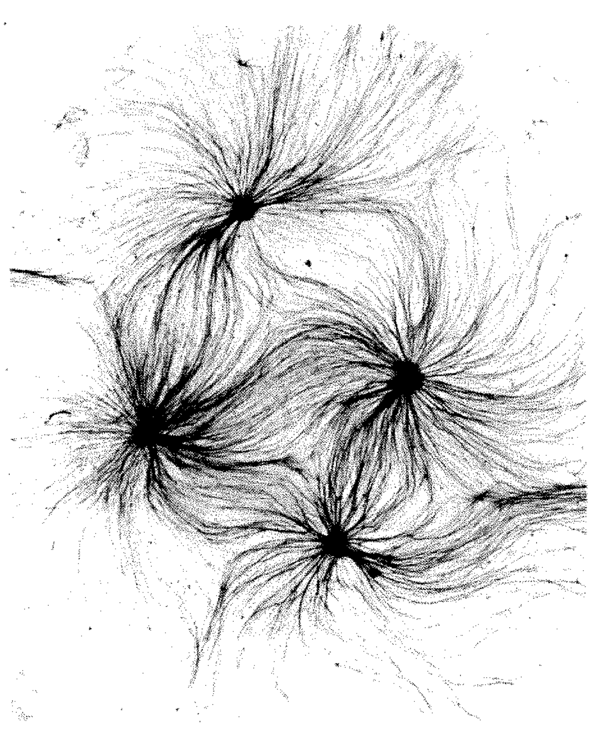

Fig. 1 Photomicrograph of superior cervical ganglion explants after 3 weeks' growth in culture. Cultures were fed with Eagle's minimal essential medium (80 vol. %), supplemented with glucose (600 mg %), human serum (10 vol. %), 150 mM KCl (10 vol. %), and nerve growth factor (20 ng ml^{-1}). The media contained 10^{-5} M 5′-fluorodeoxyuridine continuously, and 10^{-5} M cytosine arabinoside from day 2 until day 7, *in vitro*. The neuronal cell bodies are confined within the explants and the neurites, free of supporting cells, extend from each explant. Before neurite collection, the explants were removed by dissection. (MX5.)

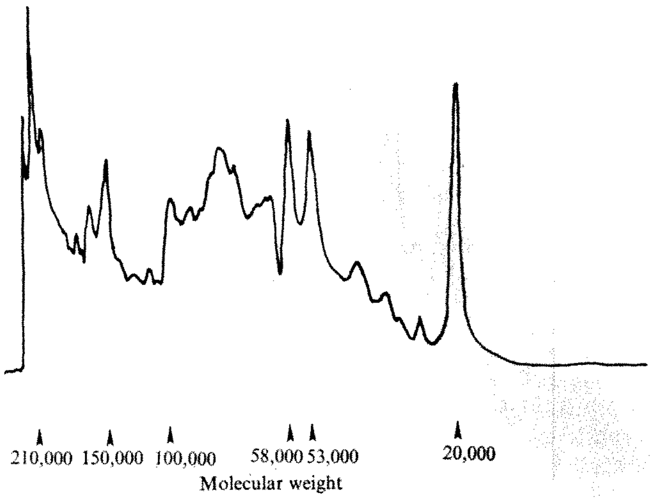

Fig. 2 Densitometric scan of a fluorograph made from contact with an SDS slab gel. The sample was composed of neurites collected from explants which had been exposed to a 2-h pulse of radioactive leucine (20 μCi ml^{-1} in medium made with leucine-free MEM and three times dialysed human serum). The polypeptides were separated by SDS-discontinuous slab gel electrophoresis on a 5–15% gradient of polyacrylamide. These radioactive polypeptides had been transported into the neurites after synthesis in the neuronal somata. The two large peaks of radioactivity at molecular weight 53,000 and 58,000 co-migrate with the α and β subunits of tubulin. The absence of a labelled peak co-migrating with actin is explained by the observation that actin is transported at a slower rate than tubulin and at this moment, has not yet entered the neurite in substantial amounts. Electrophoresis and fluorography were as described in refs 12 and 18. Molecular weight standards and assigned molecular weights were: phosphorylase A (94,000), bovine serum albumin (68,000), catalase (60,000), glutamic dehydrogenase (56,000), IgG, heavy chain (50,000), ovalbumin (43,000), aldolase (40,000), lactate dehydrogenase (36,000, α-chymotrypsinogen 25,000), IgG, light chain (23,500), myoglobin (17,200). Porcine brain tubulin was used as standards for α and β tubulin.

This experiment suggested that polypeptides similar to the α and β subunits of soluble tubulin were associated with the neuritic plasma membrane. In order to investigate the polypeptides of the plasma membrane, external labelling using iodination catalysed by glucose oxidase/lactoperoxidase was attempted. The results of such experiments are shown in Fig. 4. A relatively small number of polypeptides became labelled in conditions in which the enzymes should have remained outside the neurites (Fig. 4*a*, *c*). That the labelling pattern is due to iodination of polypeptides exposed on the cell exterior is supported by a number of control experiments: (1) the labelling is entirely dependent on the presence of the catalytic enzymes; (2) the labelling pattern which homogenised neurites exhibit is much more inclusive, with essentially all of the polypeptides demonstrated by Coomassie blue staining labelled. The most striking example of this is the heavy labelling of polypeptides co-migrating with actin, when the iodination is done on homogenised neurites as compared to the absence of label in that region after iodination of intact neurites (experiment not shown); (3) none of the media polypeptides or substrate polypeptides show an iodination pattern similar to that in Fig. 4, when examined electrophoretically. This latter control suggests that the surface-associated tubulin-like proteins are not derived from polypeptides present in the medium.

The effects of trypsin treatment on the iodination pattern further support the hypothesis that the tubulin-like polypeptides are exposed at the exterior surface of the neuronal plasma membrane. Figures 4*d* and *e* show that brief treatment with low levels of trypsin will remove the iodinatable species which co-migrate with soluble reference tubulin. This suggests a

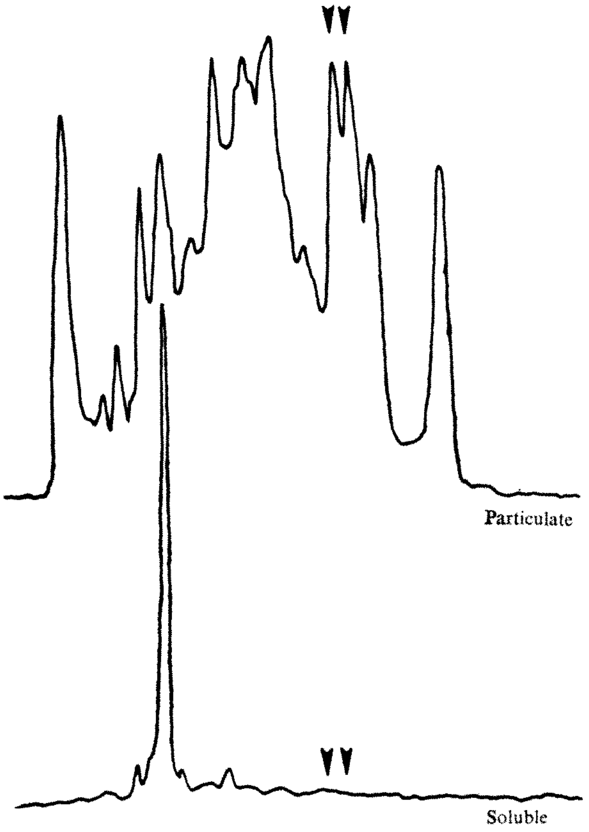

Fig. 3 Densitometric scans of fluorographs made from contact with SDS-slab gels. The samples were derived from neurites harvested from explants after 12 h of labelling with tritiated fucose (10 μCi ml^{-1} in medium made with three times dialysed serum). In the upper scan, the sample consisted of insoluble neuritic material after homogenisation in 150 mM NaCl, 5 mM sodium phosphate (*p*H 7.2), and centrifugation at 100,000*g* for 1 h. The lower scan represents the soluble neuritic material derived from the same homogenate. In the lower scan, there is no radioactivity associated with the area of the gel containing the α and β subunits of tubulin (arrows). In the particulate sample, however, polypeptides co-migrating with α and β tubulin subunits are substantially labelled. Direction of electrophoresis was from left to right. Electrophoresis and fluorography as in Fig. 2.

restricted amount of the iodinatable species, most or all of which is removed in the proteolytic treatment. Data not shown demonstrate that there are no differences in the Coomassie blue staining patterns of the samples used in Fig. 4*c*, *d*, *e* indicating the small amount of proteolysis which actually occurs during such treatment, and more importantly, that the bulk of the neuritic tubulin is unaffected while the co-migrating label is removed.

In the Laemmli SDS gel system[12], the α and β subunits of soluble tubulin are resolved and migrate at molecular weight 58,000 and 53,000, respectively. If the ionic strength of this same buffer system is increased by the addition of 300 mM NaCl, the tubulin subunits co-migrate[13]. When aliquots of the same sample of iodinated neurites are run in the two gel systems, the labelled polypeptides in the molecular weight range 50,000–60,000 always co-migrate with soluble reference tubulin subunits no matter whether the reference tubulin subunits resolve (as in the regular Laemmli system) or not (as in the high ionic strength modification). Thus, in two quite different gel systems, these two polypeptides behave similarly to soluble tubulin.

Taken together, these experiments strongly suggest and strengthen the view that tubulin-like polypeptides are present in the neuronal plasma membrane and further, that these polypeptides may be exposed on the exterior of the cell surface.

The role of such a protein may only be hypothesised at this time. It is well known that a colchicine-sensitive mechanism can control the mobility of polypeptides in the cell membrane[14]. These membrane-associated tubulin-like polypeptides may act as anchors for the membrane-associated microtubules described by a number of electron microscopists. In terms of neuronal cell biology, Levi-Montalcini *et al.* have presented evidence that a tubulin-like molecule may have a role in the recognition of nerve growth factor (NGF) at the cell surface[15]. In their study, live intact mouse neuroblastoma cells, which had NGF receptors on their surfaces, would form rosettes with

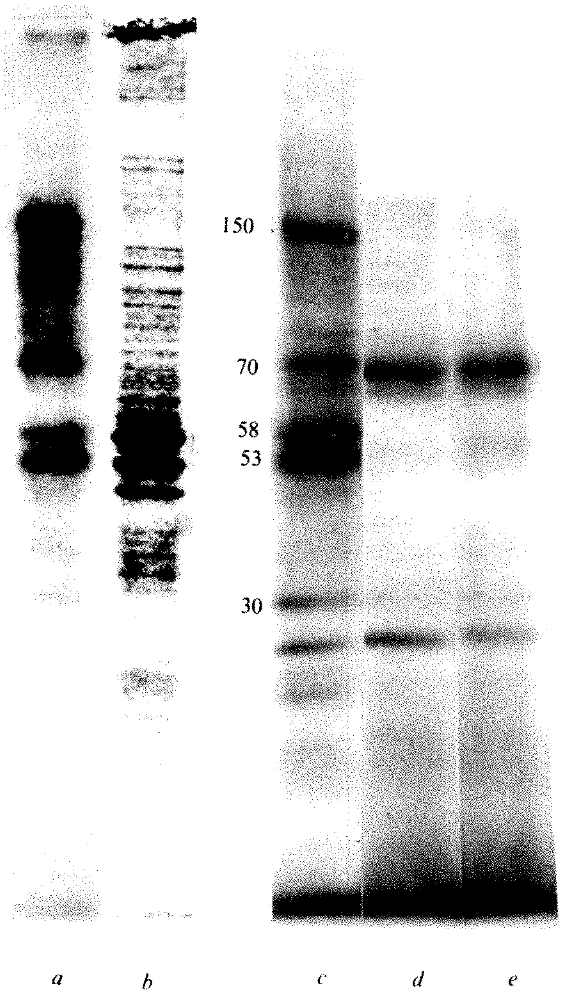

Fig. 4 Results of iodination experiments on intact neurites isolated from superior cervical ganglion explants. Panels *a*, *c*, *d*, *e* are autoradiographs of SDS-slab gels. Panel *b* is a picture of a Coomassie blue stained gel which produced the autoradiograph shown in panel *a*, and allows for molecular weight assignments of the iodinated bands. All samples consisted of neurites which had been iodinated using 5 milliunits ml^{-1} each of lactoperoxidase and glucose oxidase, 5 mM glucose, and 100 mCi ml^{-1}. Na^{125}I, in phosphate-buffered saline, *p*H 7.2. After 15 min labelling at 0 °C, samples were repeatedly washed with PBS containing excess iodide. Sample *d* consisted of neurites which had been treated with 20 μg ml^{-1} crystalline trypsin for 15 min at room temperature before iodination. Sample *e* consisted of neurites which had been treated with the same amount of trypsin after the iodination procedure. Samples *a* and *c* consisted of non-trypsin treated, control iodinated neurites. Note that the protease treatment removed the label at molecular weight 53,000 and 58,000, which co-migrated with α and β tubulin. Also removed by protease treatment were prominently labelled polypeptides migrating at molecular weight 150,000 and 30,000. In sample B, the prominent polypeptide band below the heavy bands at molecular weight 53,000 and 58,000 co-migrated with purified muscle actin. Note the absence of any iodine incorporation into this major polypeptide in the autoradiographs of the iodinated neurites. The numbers in the centre of the figure indicate approximate molecular weight $\times$ 10^{-3}, as determined by comparison with polypeptides of known molecular weights. Electrophoresis was as described in ref. 12. Autoradiography was accomplished by exposing Kodak RPR-54 film to the stained and dried slab gel.

NGF-coated red cells. This rosette formation presumably represented the hormone–receptor interaction. Antibody prepared against soluble brain tubulin could prevent rosette formation in their experiments.

Actin and myosin have now been shown to be associated with the surface membrane in a variety of non-muscle cells[16,17]. The identification of tubulin in the surface membrane of neurones suggests that it will be necessary to expand our ideas of the roles this protein may play in cell function.

I thank Drs R. P. Bunge and L. Glaser for their advice during the course of this work which was carried out in the laboratory of Dr Bunge. This work was supported by grants from NIH and the Washington University Medical Scientist Training Program.

Type I and type II cyclic AMP-dependent protein kinase as opposite effectors of lymphocyte mitogenesis

THE role of cyclic AMP in the regulation of cell growth and differentiation has been extensively investigated in many cell types following various growth stimuli[1,2]. In recent years, peripheral blood lymphocytes treated with antigens[3], plant lectins[4], lipopolysaccharides[5], or periodate oxidation[6] have served as a model system for assessing whether cyclic AMP is involved in the regulation of the mitogenic response promoted in these cells by the above classes of agents[7,8]. There are two conflicting hypotheses, as outlined by Friedman[1], concerning the role of cyclic AMP in lymphocyte proliferation. The first hypothesis suggests that the increase in cyclic AMP levels following mitogen stimulation[8] and the subsequent increase in ^{32}P incorporated into Fl histones[9] and certain cystosol proteins[10] implicates cyclic AMP as a positive mediator of mitogenesis in lymphocytes. The other hypothesis reasons that cyclic AMP inhibits proliferation, and this hypothesis is supported primarily by observations from several laboratories that raising the intracellular cyclic AMP level through the use of phosphodiesterase inhibitors[11], prostaglandins[12], or cyclic AMP analogues[11,13–15] effectively inhibits mitogen-stimulated RNA and DNA synthesis. We present here evidence that may help resolve this apparent paradox. Incubation of Ficoll–Hypaque purified human peripheral blood lymphocytes with concanavalin A (conA) leads to the activation of only type I cyclic AMP-dependent protein kinase in these cells even though there are significant amounts of both type I and type II kinase present. But, the addition of dibutyryl cyclic AMP (DBcAMP) to the conA-stimulated lymphocytes at a concentration sufficient to block the synthesis of RNA and DNA results in the activation of both type I and type II cyclic AMP-dependent protein kinase. It therefore seems likely that while the activation of type I protein kinase represents a positive component in the progression of events promoted in a lymphocyte by a mitogenic signal (as it does in other cell types in which a trophic response is evoked), the activation of type II protein kinase (or perhaps types I and II in concert) represents a mechanism by which a negative influence can be imposed on the pro-

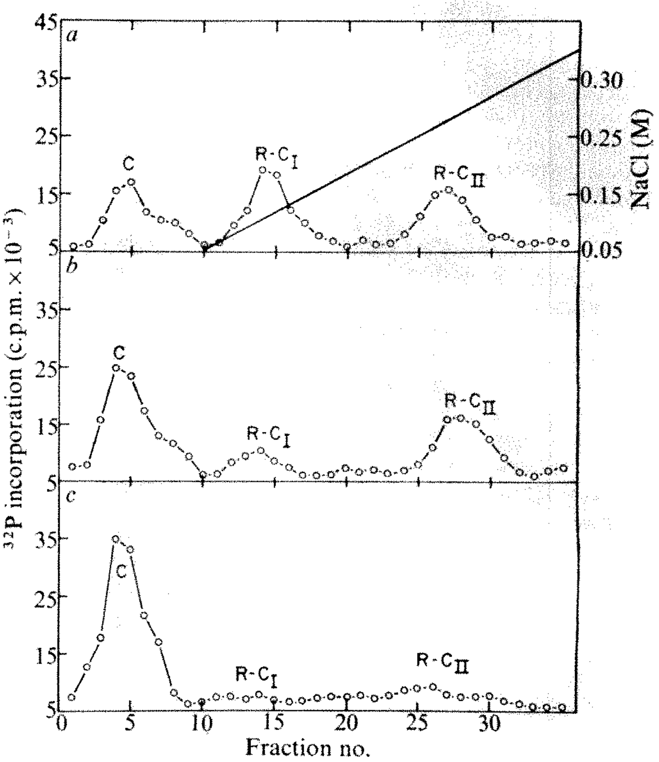

Fig. 1 Type I and type II protein kinase activation following con A and DBcAMP administration. Human peripheral blood lymphocytes were isolated from heparinised venous blood from healthy male donors by flotation on Ficoll–Hypaque (Litton Bionetics) and washed three times using phosphate buffered saline as described previously[23]. The cells were suspended in 10 ml of Eagles medium at a density of 2 × 10^6 per ml and preincubated at 35 °C overnight. Con A was added at 10 μg ml^{-1} resulting in maximal rates of RNA and DNA synthesis at 48 and 72 h respectively. Previous experiments using supernatant determinations of the without cyclic AMP/with cyclic AMP protein kinase activity ratio (data not shown) indicated that total cyclic AMP-dependent protein kinase activation was greatest after a 4-h incubation with con A. DBcAMP 10^{-5} M when added concomitant with con A blocked by greater than 90% the increase in ^{3}H-uridine and ^{3}H-thymidine incorporation into acid-precipitable material normally seen at 48 and 72 h. C^6-amino alkyl Agarose chromatography of unstimulated (*a*), con A (*b*), and con A and DBcAMP (*c*) stimulated lymphocytes (4-h incubations) was performed as described by Rangel-Aldao and Rosen[16] with modifications. The C^6-Agarose was prepared according to Shaltiel[25] and 1-ml columns of resin were equilibrated with 15 mM sodium–potassium phosphate, *p*H 6.8, 1 mM EDTA, 0.5 mM methylisobutylxanthine, 5 mM β-mercaptoethanol, 5 mM NaFl, and 60 mM NaCl. This salt concentration was sufficient to allow the free catalytic subunit to pass through the column while the regulatory subunits and type I and type II holoenzyme were bound. The capacity and the required initial salt concentration was determined with purified C, R_IC (type I), and $R_{II}C$ (type II) for each batch of resin. 60 × 10^6 cells were sonicated for 10 s in 300 μl of the above buffer at 0 °C and 250 μl of the sonicate applied to the column. The column was rapidly washed for 10 fractions (200 μl per fraction) with buffer containing 60 mM NaCl and a gradient from 60 to 350 mM NaCl (4 ml of each) begun. Aliquots (50 μl) of each fraction were assayed for kinase activity with mixed calf thymus histone as substrate in the presence of 5 μM cyclic AMP (ref. 19). Purified regulatory and catalytic subunits showed no reassociation when chromatographed in these conditions.

liferative process by the generation of abnormally high levels of intracellular cyclic AMP.

Human peripheral blood lymphocytes were purified and cultured as described in the legend to Fig. 1. Using C^6-amino alkyl Agarose chromatography, originally used by Rosen and coworkers to study isozymes of cyclic AMP-dependent protein kinase [16,17], the two isozyme forms (R_IC and $R_{II}C$, inactive holoenzyme forms) were rapidly separated from each other and from the dissociated free catalytic subunit (C), that is, activated protein kinase. Con A addition, which promotes an increase in cyclic AMP (ref. 8), activates only type I of the kinase. Fig. 1*a*, *b* shows that kinase activity decreases in those fractions containing type I holoenzyme and appears in the flow-through fractions which correspond to free active catalytic subunit. Addition of DBcAMP to the con A-stimulated lymphocytes further reduces kinase activity from the elution profile which corresponds to type II holoenzyme and again the activity is recovered as catalytic subunit in the flow-through fractions (Fig. 1*c*).

The mechanism by which the activation of type II kinase by DBcAMP in lymphocytes might lead to inhibition of mitogen-induced proliferation is not immediately apparent. However, the activation of both forms of the kinase rather than the selective activation of type I at a time when the cell is preparing to synthesise protein, RNA, and DNA in a specific series of events leading to eventual cell division may interfere with any of a multitude of parameters mediating this process. These could include Ca^{2+} fluxes, ribosome aggregation, cyclic GMP events, and/or transport of precursors or essential serum factors from the media.

It is becoming increasingly evident that type I and type II cyclic AMP-dependent protein kinase may have separate functions in the cell. They have specific expression patterns during cell cycle[18], cardiac hypertrophy[19], and during the growth and differentiation of certain tissues[20]. Lee *et al.*[20] have shown that during testicular ontogeny, type I protein kinase is present and the appearance of differentiated cell types in the testis is concomittant with an increase in type II protein kinase. In addition, the two forms of protein kinase have different regulatory properties. Rosen[16] has shown that only the regulatory subunit of type II holoenzyme is phosphorylated, greatly reducing its ability to reassociate with free catalytic subunit. A separate role was postulated for this isozyme based on this unique phosphorylation event. In those cell culture cells in which cyclic AMP events have been studied, cyclic AMP increases markedly during G_1 phase of the cell cycle, decreases at the G_1/S border, and increases again in G_2/M. Addition of DBcAMP and a phosphodiesterase inhibitor early in G_1 prevents Chinese hamster ovary cells from progressing from G_1 into S phase[21]. In fact, it also results in differentiation as assessed by cell elongation and increased microtubular structures[21,22].

Therefore, while activation of type I cyclic AMP-dependent protein kinase represents a positive component in events promoted in the lymphocytes by a mitogenic signal, the activation of type II protein kinase (or perhaps types I and II in concert) represents a mechanism by which a negative influence can be imposed on the proliferative response by the generation of an abnormally high intracellular cyclic AMP concentration. This study for the first time points to the complexity of cyclic AMP mediation, since it acts through two specific enzymes regulated by alterations in cyclic AMP levels.

Further studies of tissues at various stages of differentiation in regard to pools of protein kinase, type I and type II, as well as the activation patterns of these kinases after intracellular changes in cyclic AMP in response to hormones which are specific stimuli and to the addition of cyclic nucleotide analogues and phosphodiesterases which are nonspecific stimuli are necessary to ascertain if these parameters operate in the control of growth and differentiation.

Chinese hamster cell mutant with defective mitochondrial protein synthesis

STABLE mutations affecting mitochondrial functions have been reported in lower eukaryotes[1–7] and higher organisms[8–11]. We have described a procedure to select mutants with defective patterns of oxidative energy metabolism from established Chinese hamster fibroblasts[8], which seem to satisfy most of their energy needs from glycolysis[6]. We describe here a mutant which has properties reminiscent of the petite phenotype of yeast ρ^- mutants[5,13,14]: a defect in mitochondrial protein synthesis leads to multiple enzymatic deficiencies.

The mutant cells, V79-G7, were characterised as respiration-deficient by the following criteria[8–10]. (1) The rate of oxygen consumption by whole cells is about 10% that of wild-type cells. (2) There is no appreciable release of $^{14}CO_2$ from 2-^{14}C-pyruvate or 5-^{14}-C-glutamate (conversions requiring an active and complete Krebs cycle). (3) The cells behave as auxotrophs for CO_2 and asparagine, compounds normally derived from the Krebs cycle. And (4), when galactose, a slowly fermentable carbon source, is substituted for glucose in the medium, the cells die overnight. In these respects V79-G7 cells resemble all other respiration-deficient fibroblasts isolated from the parental line[8]. A unique property of this mutant was a reduced capacity of isolated mitochondria to respire in the presence of succinate or α-glycerolphosphate. Succinate dehydrogenase activity in mitochondria was much less reduced (Table 1). These results focused our attention on the electron transport chain between coenzyme Q and oxygen.

The terminal enzyme complex of the electron transport chain is cytochrome oxidase which can be assayed in purified mitochondria using exogenous, heterologous, reduced cytochrome *c* as substrate[15]. In Fig. 1 a rate constant,

Table 1 Biochemical activity of V79 and V79-G7 mitochondria

	Activity per mg protein V79	V79-G7	% of control
Succinate oxidation	1180 ± 120 nmol O_2 h^{-1}	400 ± 90 nmol O_2 h^{-1}	33.9 ± 7.6
α-glycerol phosphate oxidation	1320 ± 190 nmol O_2 h^{-1}	700 ± 40 nmol O_2 h^{-1}	53.0 ± 3.0
Cytochrome oxidase activity	24.4 ± 12.3 ml min^{-1}	1.6×0.8 ml min^{-1}	6.6 ± 3.3
ATPase activity (oligomycin-sensitive)	380 ± 56 nmol P_i h^{-1}	44 ± 11 nmol P_i h^{-1}	11.6 ± 2.9
Succinate dehydrogenase	23.7 nmol mg^{-1}	17.0 nmol min^{-1}	72

Assays of selected activities of isolated mitochondria. Cells were grown in Dulbecco's modified Eagle's medium (DME) with the following additions: 45 μg ml^{-1} asparagine, 4 mg ml^{-1} glucose, 20 mM HEPES buffer, *p*H 7.5, 10% foetal calf serum (Irvine Scientific) and alternating antibiotics. Mitochondria were isolated following the procedure of White and Tewari[25]. Washed cells were homogenised in a Dounce homogeniser in buffer containing 250 mM sucrose, 2 mM EDTA, 50 mM Tris, *p*H 7.4 (SM buffer), containing 1% bovine serum albumin (BSA). After removal of the nuclei the mitochondria were pelleted in the SS34 Sorvall rotor (10,000 r.p.m., 10 min) washed once by resuspension in SM buffer plus 1% BSA and repelleted as above. All manipulations were carried out at 0–4 °C. For the measurement of oxygen consumption mitochondria were resuspended in 2 ml SM buffer plus 1% BSA, placed in a thermostated oxygen electrode chamber, and oxygen consumption was measured as described previously[9]. The cytochrome oxidase assay is described in the legend to Fig. 1. The oligomycin-sensitive ATPase was found to be most reproducibly measured after treatment of the mitochondria at *p*H 9.2, in SM buffer, at room temperature[26]. 100 μl of mitochondrial suspension was then mixed with 350 μl of Tris buffer (25 mM, *p*H 9.2) containing Mg^{2+} (3.3 mM), plus or minus oligomycin (44.4 μg ml^{-1}), and finally 50 μl of ATP (50 mM) was added to the mixture. After 10 min at 30 °C the reaction was terminated by addition of trichloroacetic acid (final concentration 10%) and inorganic phosphate determined by the method of Fiske and Subbarow[27]. Approximately 60% of the total ATPase activity observed in wild-type mitochondria was inhibitable by oligomycin. Mg^{2+} ions were essential for all observed activities.

assumed to be proportional to cytochrome oxidase activity is plotted against amounts of Lubrol added to the mitochondrial preparation. Treatment of wild-type mitochondria with detergent uncovered measurable activity, whereas in the mutant, enzyme activity remained very low, at most 6.6% relative to wild type.

These results were confirmed by measurements of the absorbance spectra of fully reduced whole cells in the wavelength range 400–630 nm (Fig. 2). The most notable differences between mutant and wild-type cells were observed at 440 nm and at 600 nm corresponding to the Soret band and the α band, respectively, of the cytochromes *aa*$_3$. Cytochromes *aa*$_3$ seem to be absent in the mutant cells. Although uncertainties of the baseline make quantitative comparisons difficult, there seems to be no decrease in the cytochrome *c* content of the mutant cells, as judged by the absorption peak at 550 nm. But, the shoulder at 560 nm, the region of absorption of cytochrome *b*, seems to be reduced in the case of the mutant cells.

From work done in yeast and *Neurospora*, it is known that the cytochrome oxidase and cytochrome *b* contain subunits which are synthesised inside the mitochondria, whereas cytochrome *c* is synthesised exclusively in the cytoplasm[13,14,16,17]. Another enzyme known to have several subunits synthesised within the mitochondria is the oligomycin-sensitive ATPase (refs 13, 14, 18). We assayed this enzyme in mitochondria and found that its activity, like that of cytochrome oxidase, was greatly reduced in the mutant cells (11.6% relative to wild type, see Table 1).

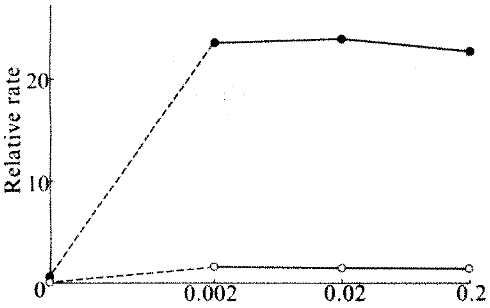

Fig. 1 Cytochrome oxidase activity in detergent-treated wild-type and mutant mitochondria. After a 10-min pretreatment of the mitochondria in SM buffer with various concentrations of Lubrol the reactions were initiated by addition of excess reduced cytochrome *c* from beef heart[12] and the absorbance was measured at 550 nm with a recording spectrophotometer. Experiments were performed at 25 °C. The observed rate constants were normalised to the same concentration of total mitochondrial protein in the reaction mixture. Absolute rates are given in Table 1.

The properties of the mutant described so far, and the similarity to the phenotype of the ρ^- mutants of yeast, prompted us to examine mitochondrial protein synthesis *in vivo* in wild-type and V79-G7 cells. In these experiments cytoplasmic protein synthesis was inhibited by cycloheximide, and the cells were then labelled with ^{3}H-leucine, followed by a chase with cold leucine. In wild-type cells cycloheximide, at 100 μg ml^{-1}, inhibited total incorporation of ^{3}H-leucine into whole cells by 95–97%. Purified mitochondria were dissolved in buffer containing SDS and β-mercaptoethanol, and their proteins were fractionated electrophoretically on sodium dodecyl sulphate–polyacrylamide slab gels (Fig. 3). The wild-type pattern shows at least seven peaks of radioactivity, corresponding to a range in size from 10,000 to 44,000 MW (Fig. 3*a*). In contrast, an equivalent amount of mitochondrial protein from the mutant cells gave no such distinctive profile (Fig. 3*b*). Only traces of the 22,500 and 25,000 peaks were visible. The amount of ^{3}H-leucine incorporated per milligram of protein of the mitochondrial fraction was slightly greater than one-third of that in wild-type cells. Most of the radioactivity

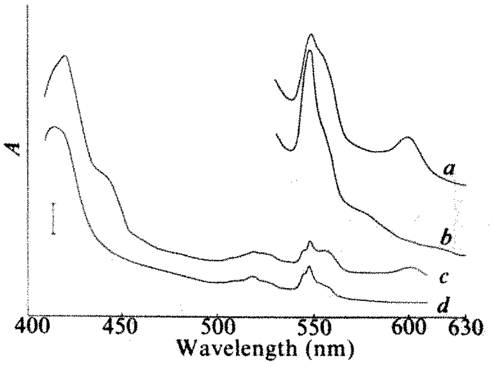

Fig. 2 Absorption spectra of reduced, whole cells. A suspension of cells in buffer containing NaCl (137 mM), KCl (5 mM), Na_2HPO_4 (0.7 mM), Tris (25 mM), *p*H 7.3, was reduced by addition of a few grains of dithionite and then frozen in quartz spectrophotometer cuvettes at a density of 10^7 cells per ml. Absorption spectra were recorded at liquid nitrogen temperature in a Cary 14 spectrophotometer, with the output from the photomultiplier fed into a PDP 8/1 computer for the summation of multiple scans over the wavelength region indicated. Two independent experiments are shown: wild-type (*c*) and mutant cells (*d*) were scanned from 410 to 610 nm, and the experiment was repeated with different batches of cells: wild-type (*a*) and mutant cells (*b*), with a scan from 530 to 630 nm. Approximately equal numbers of wild-type and mutant cells were compared in each experiment. The bar represents an absorbance change of 0.1 (curves *c* and *d*), and the scale is changed by a factor 4 for curves *a* and *b*.

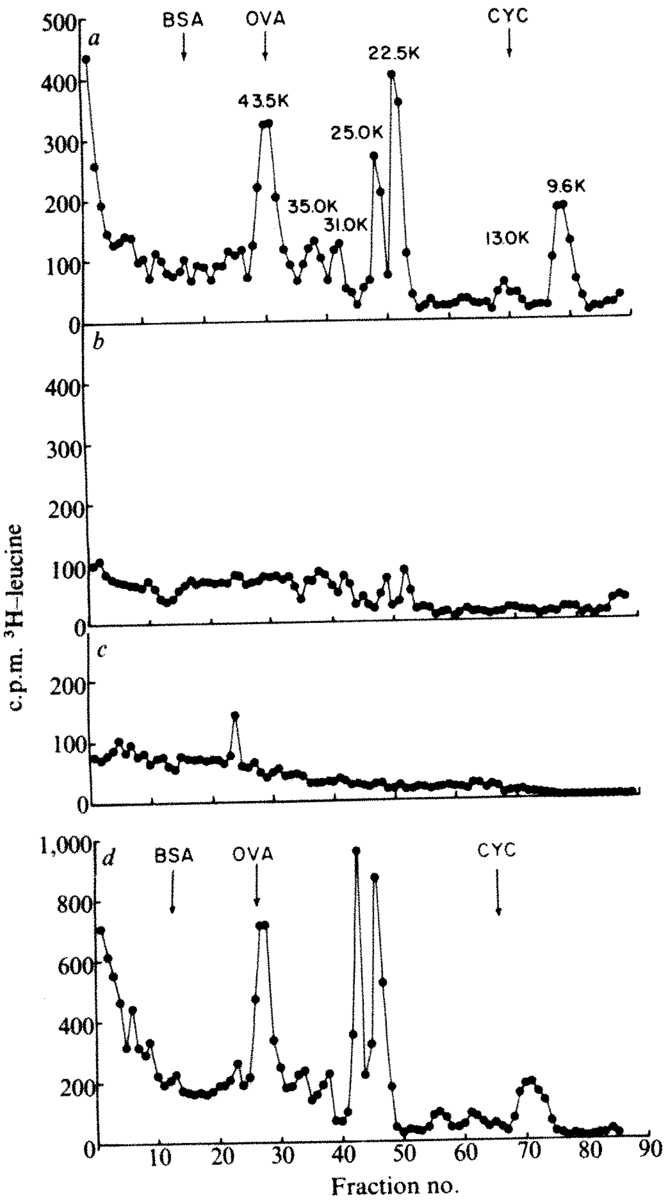

Fig. 3 Protein synthesis in wild-type and mutant mitochondria. Cells grown in roller bottles (~ 5–7 × 10^7 cells total) were incubated for 30 min with 100 μg ml^{-1} cycloheximide, and then labelled for 2 h with ^3H-leucine (20 μCi ml^{-1}; specific activity 57.4 Ci $mmol^{-1}$), followed by a 30-min chase with an excess of cold leucine (100 μg ml^{-1}). The mitochondria were purified first as described in the legend of Table 1, then loaded on top of linear sucrose gradients (1.03–1.60 M sucrose, 50 mM Tris, *p*H 7.4, 2 mM EDTA) and centrifuged at 4 °C in a Beckman SW50.1 rotor at 40,000 r.p.m. for 2 h. A narrow band of material was always observed at a density of 1.17 g cm^{-3}, and a peak of radioactivity was associated with this band. The band was removed, the material pelleted by centrifugation, dissolved at 90–100 °C in buffer containing Tris-HCl (62.5 mM, *p*H 6.8), glycerol (10% w/v), β-mercaptoethanol (5% w/v), sodium dodecyl sulphate (SDS, 2.3% w/v), and stored at –20 °C until ready for use in electrophoresis. Samples were run on 12.5% polyacrylamide slab gels (1 mm thickness) containing Tris-HCl (37.5 mM, *p*H 8.8) and SDS 0.1% w/v). The gels were stained with 0.1% Coomassie blue in 50% trichloroacetic acid for 20 min, destained in 7% acetic acid, and then cut into 1-mm sections with a gel slicer made of a battery of razor blades. Slices were incubated overnight in 0.5 ml NCS solubiliser (Amersham/Searle) before being counted in 5 ml of toluene-based scintillation fluid. Bovine serum albumin (BSA), ovalbumin (OVA) and cytochrome *c* (CYC) were run on the same gels in parallel tracks as molecular weight markers. Profiles for mitochondria from: *a*, V79 wild type; *b*, V79-G7; *c*, V79 pretreated with chloramphenicol at 100 μg ml^{-1} for 5 h before addition of label, *d*, CCL16-B2, a mutant lacking NADH-oxidase activity. Radioactivity content: *a*, 469 c.p.m. $μg^{-1}$; *b*, 196 c.p.m. $μg^{-1}$; *c*, 158 c.p.m. $μg^{-1}$; *d*, 836 c.p.m. $μg^{-1}$.

was distributed as a background or relatively high molecular weight material.

To prove that the observed pattern of protein synthesis is indeed due to mitochondrial protein synthesis, we tested its sensitivity to the specific inhibitor chloramphenicol (Fig. 3*c*). The effect of this inhibitor is very marked, although we found it necessary to pre-incubate the cells for some time with the drug before the addition of ^3H-leucine. With wild-type V79 cells we found approximately 64% inhibition of cycloheximide-resistant ^3H-leucine incorporation as well as an altered profile (Fig. 3*c*). Pretreatments longer than 5 h failed to reduce the level of incorporation further. We tentatively conclude that there is a background of chloramphenicol-resistant protein synthesis in this system (which may in fact be due to incomplete inhibition of cytoplasmic synthesis) which accounts for approximately one-third of the incorporation seen in the absence of the drug.

The abnormal pattern of mitochondrial protein synthesis in V79-G7 cells is not a general characteristic of respiration-deficient Chinese hamster fibroblasts. Figure 3*d* shows a profile corresponding to mitochondrial protein synthesis in a mutant defective in NADH-coenzyme Q reductase[9,10]. Except for a difference in specific activity there is no significant difference between this pattern and that observed for wild-type cells, and similar results were observed with yet another respiration-deficient mutant representing a third complementation group (results not shown). We conclude that the defect in mitochondrial protein synthesis in V79-G7 cells is unique.

We do not yet know whether the mutation in the V79-G7 cells is nuclear or cytoplasmic. In fact, this mutant is very similar in phenotype to a nuclear yeast mutant (strain M126) described by Colson, Labaille and Goffeau[19]. Mitochondrial DNA is known to code for a limited number of macromolecules including ribosomal RNAs, transfer RNAs and probably certain subunits of cytochrome oxidase, cytochrome *b*, and the oligomycin-sensitive ATPase (refs 13, 14, 16, 17, 20), while most if not all of the ribosomal proteins, RNA polymerase, aminoacyl-tRNA synthetases, and other protein factors involved in protein synthesis are thought to be coded for by nuclear genes and imported from the cytoplasm[21,24].

Studies are in progress aimed at (1) the fusion of enucleated, cytoplasmically marked (chloramphenicol-resistant) hamster cells with the V79-G7 cells; (2) measurement of the spontaneous reversion rate; and (3), physical characterisation of the mitochondrial DNA from the mutant. Further investigation of this mutant may allow further comparison of mitochondrial biogenesis in eukaryotic cells such as yeast and in mammalian cells, and of the contributions which the nuclear and mitochondrial genomes make to the assembly of the organelle.

This work was supported by the US PHS and the American Cancer Society. We thank Dr Butler for use of his spectrophotometer.

Interferon production during lymphocytic choriomeningitis virus infection of nude and normal mice

SEVERAL reports[1–6] have indicated that lymphocytic choriomeningitis virus (LCMV) infection of mice or cultured cells is not associated with interferon production. But, as was found later[7] the methods used may not have been sensitive enough to detect interferon in tissues of virus infected animals. In contrast to these earlier observations, mice acutely infected with M-P virus, a virus closely related to LCMV (ref. 8), have been reported to produce interferon[9]. We observed a more intense and prolonged interferon response to a virus inducer in nude athymic mice (Fig. 1) as others[10] have with synthetic double-stranded nucleic acids. Therefore, it seemed reasonable to study LCMV infection of nude animals carefully for interferon production in serum and infected organs. Parental strains and nude heterozygotes (*Nu*/$^+$) were studied as well as the homozygous nude (*Nu*/*Nu*) animals. The results presented here indicate that interferon is made in greater quantity and persists longer during infection of *Nu*/*Nu* than of parental and *Nu*/$^+$ mice.

Figure 1 presents results following intravenous inoculation of live Newcastle disease virus in *Nu*/*Nu*, *Nu*/$^+$ and BALB/c parental strains, as well as similar parental and nude mice of a CBA background. Results from two separate serum pools involving 10 animals each were averaged for both comparative studies. It can be seen that the parental responses are consistently lower than those of nude animals at all time points, particularly at 12 and 24 h after virus inoculation. The *Nu*/$^+$ mouse in our studies with the CBA strain resembles the nude mouse but is intermediate in its responses in the BALB/c animals. These findings resemble those reported by Yokota, *et al.*[10] with poly I : C injection of BALB/c, nude and heterozygote animals, and indicate that interferon production can occur in the absence of thymus dependent lymphocytes.

Studies with acute infection demonstrated high interferon titres in the spleen and serum in all 6-week-old animals studied 4–7 d after intracerebral (i.c.) inoculation with 100 LD$_{50}$ of LCMV, Armstrong strain (Table 1). This time period corresponds to the period of maximal T-cell activity and other immunopathological responses. In the nude animals there was an increase in spleen and serum levels of interferon, four- and threefold respectively on the seventh day after infection compared with the fourth day after infection. In contrast, at least an eightfold reduction in interferon levels was observed in the spleens and serum from *Nu*/$^+$ and parental BALB/c animals studied at similar times (Table 1). The antiviral material extracted from the spleen and serum was shown to be interferon by its stability to *p*H 2 for 1 h at 4 °C, lack of sedimentability at 100,000*g* for 2 h, its inactivation by trypsin (1 mg ml^{-1}, 37 °C 1 h), its immunospecific neutralisation on exposure to antisera to L cell interferon[12] and its lack of protection of human skin fibroblasts challenged with vesicular stomatitis virus. Furthermore, no protection was observed when the antiviral substance was applied to L cells for only a short period (1 h) before virus challenge even though it was maintained on monolayers during plaque development.

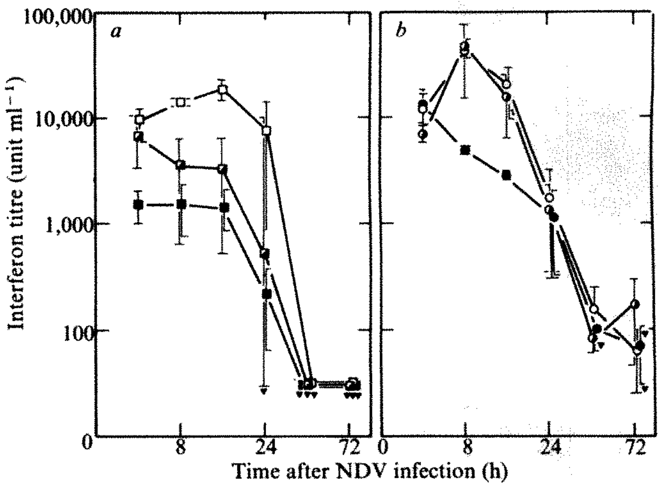

Fig. 1 Production of interferon in *Nu*/*Nu*, *Nu*/$^+$ and BALB/c or CBA parental strains. *a*, BALB/c, *Nu*/*Nu* and *Nu*/$^+$; *b*, CBA, *Nu*/*Nu* and *Nu*/$^+$. Each point represents the mean of two experiments in which serum from 10 animals was pooled for each experimental observation. The serum was collected at the indicated times after inoculation of 20-g mice with 1 × 10^8 plaque-forming units of live Newcastle disease virus (NDV) intravenously. Interferon titres represent the reciprocal of the dilution of serum giving 50% inhibition of vesicular stomatitis virus plaque formation in the L$_{929}$ monolayers growing in 60-mm plastic plates as described elsewhere[11]. The mean and range of replicates is shown by the bracketed bar. Symbols: in *a*—■, homozygote BALB/c parent (BALB/c); ◪, BALB/c nude heterozygote (*Nu*/$^+$); □, nude homozygote (*Nu*/*Nu*). In (*b*), ●, CBA parent (CBA); ◑, CBA nude heterozygote (*Nu*/$^+$); ○, nude homozygote (*Nu*/*Nu*). In all strains, interferon titres in the serum at zero time were less than 20 units per ml.

Interferon levels in the liver and kidney were similar in all animals 4 d after LCMV inoculation, while at the seventh day post-infection, nude mice showed higher levels of interferon when compared to *Nu*/$^+$ and parental mice. Despite high virus titres and in contrast to certain other murine viral encephalidites, interferon titres in the brain were low and indistinguishable in all three types of animal. It is of interest that there were higher virus titres in spleen, liver and kidney tissues of nude mice 7 d after infection as compared with *Nu*/$^+$ and BALB/c animals. The nude animals also survived acute LCM infection in contrast to the parental and *Nu*/$^+$ animals.

These studies demonstrate that mice acutely infected with Armstrong strain of LCMV make interferon and that acutely infected T cell-deficient mice make greater amounts of interferon, particularly at the sixth and seventh days after initiation of infection, concomitant with their survival. It has been shown by various depletion and reconstitution studies that T-derived lymphocytes sensitised to LCMV (refs 14–16) as well as antibody to LCMV and complement[17] are associated with tissue injury in acute or chronic LCMV infections[13]. The transfer of sensitised spleen cells[18] is associated with significant decreases in viral

Table 1 Interferon and virus titres after LCMV infection of BALB/c, *Nu/Nu* and *Nu/*$^+$ mice

		Interferon and virus titres		
Organ	Day after infection	*Nu/Nu*	*Nu/*$^+$	BALB/c

Acute infection was induced at 6 weeks of age with 100 LD$_{50}$ of LCMV i.c.

*Units of antiviral activity per gram of tissue or ml of serum as determined by titration of a pool obtained from five mice.

†Figures in parentheses represent virus titre in PFU per gram of organ as measured by BHK cell monolayers (results are an average of five individual single organ titrations).

‡Animals surviving/animals challenged. No homozygote nude mouse died of acute infection. With both heterozygotes and parental strains, approximately 50% died by day 7, 80–90% by day 8, and all by day 10.

titres and transfer of sensitised spleen cells[18] or depletion of complement[17] is associated with enhanced survival, although the bulk of evidence indicates that T-derived lymphocytes have a major role in survival and/or immunopathological injury. The observations reported here suggest that high tissue interferon levels in the nudes may perhaps also have a protective role in this virus infection. With recent observations[19–24] of an immunoregulatory action of interferon, it is possible that interferon may directly modulate some of the altered immunological responses observed in LCMV infected nude compared with controls. Unfortunately, our findings provide no direct evidence for this possibility. In addition, we found that BALB/c and *Nu/*$^+$ mice dying of acute LCMV infection have high titres of virus in their brain tissues together with low levels of interferon and abundant tissue injury. The latter results contrast with the high titres of both interferon and virus found in other tissues and modify the alternative interpretation that interferon production is just a concomitant of high concentrations of LCMV.

The antiviral substance we have observed in this report and have identified as interferon should be differentiated from the inhibitor of virus replication observed by Veltri and Kirk[25] in animals acutely infected with LCMV. Their inhibitor was present in higher titre in the brain than in the spleen and was inactivated by *p*H 2 exposure. It also demonstrated activity on human cells. Furthermore, the action of their inhibitor did not persist in the treated cells and was eliminated with a media change whereas ours was not.

In summary, our studies have shown that nude mice have higher titres of interferon in their spleens and serum during LCM infection concombinant with higher virus titres in various tissues and their survival from this infection. The significance of increased interferon production in the survival of these animals remains to be determined. Their survival is undoubtedly favoured by their inability to mount T lymphocyte mediated immunopathological responses.

Immunological tolerance and tumour allografts in the brain

THE brain has been considered to be an immunologically privileged site with regard to tissue transplantation. In addition, a loss of 'tumour surveillance' due to a weakening of the immune system in the brain has been postulated. The data on the brain as a privileged site are not unequivocal, however. The evidence for and against this thesis has been discussed by Woodruff[1] and Lance[2]. Barker and Billingham[3] also speculated that "reports that the brain can prevent implanted homografts from inciting sensitivity because it lacks a lymphatic drainage, thus having no afferent pathway of the immunological reflex, are more equivocal". The need for a critical re-evaluation of the brain as a privileged site has been stressed. We report here a study of the possible action of immunological tolerance in the brain and of the sensitivity of normal rats and tolerant rats to inoculation of allogeneic tumour cells into the brain. We show that transplantation tolerance is involved even in the brain; thus demonstrating the presence of specific immunity following inoculation of tumour cells into the brain. This finding suggests that previously held views of the brain as a privileged site may not be entirely valid and that specific immune processes are accomplished in the central nervous system.

AVN strain rats were used as recipients. The donors were Lewis strain rats, differing from the AVN recipients in H-1 plus non-H-1 antigens. Immunological tolerance was induced in newborn AVN recipients by the intravenous injection of $40–45\times10^6$ bone marrow cells from Lewis donors. Skin grafts from Lewis rats were transplanted 2 months after birth. Tumour cells which were inoculated into the brains were obtained from the culture of a virogenic sarcoma RSL. The RSL sarcoma was induced in a newborn Lewis rat by injection of the Schmidt–Ruppin strain of Rous sarcoma virus[4]. 5×10^3–5×10^6 tumour cells in a volume of 0.05 ml of Eagle's medium were injected with a microsyringe into the occipital lobe in the right hemisphere 1.5– [illegible] in depth of 4-month-old tolerant and untreated control AVN recipients and syngeneic Lewis recipients. After tumour cell inoculation, the animals were inspected daily and the effect of tumour growth was evaluated by death of the animals. Some animals were taken for histological examination.

The results show that the action of transplantation tolerance extends even to the brain. While untreated animals were resistant to tumour cell inoculum, except for the largest dose of 5×10^6 cells, all of the tolerant animals, like the syngeneic recipients, died after even the smallest dose of 5×10^3 cells (Table 1). Some of the non-tolerant animals died within 5–11 d of allotransplantation of the largest dose of tumour cells, whereas deaths in tolerant and syngeneic recipients of the smaller doses occurred at a slower rate (Table 2). The resistance of untreated animals to the inoculated tumour allografts was immunologically specific, as it was abolished by the induction of allogeneic tolerance. When large doses of tumour cells were inoculated into the brain some non-tolerant recipients died. RSL tumour cells injected into the muscle of the hind feet of adult AVN rats in amounts up to 10^7 cells did not induce distinct tumour growth. In 2-month-old rats the dose of 10^7 cells gave rise to tumours, but these regressed within 16 d and no animals died.

Table 1 Mortality of allogeneic normal and tolerant rats, and of syngeneic rats, following inoculation of tumour cells into the brain

No. of injected tumour cells from Lewis rats	Allogeneic AVN recipients Untreated	Allogeneic AVN recipients Tolerant	Syngeneic Lewis recipients Untreated
5×10^3	0/10*	5/5	9/9
5×10^4	1/10	8/8	NT†
5×10^5	0/10	NT	NT
10^6	0/20	10/10	5/5
5×10^6	14/24	NT	NT

*Numerator, number of dead animals; denominator, total number of animals.
†NT, Not tested.

Thus, tumour tissue allografts grew relatively better in the brain than in other sites; this seems to agree with the findings of Murphy and Sturm[5], who investigated the survival of tumour xenografts. Our observations that tumour allografts in the brain are more fatal than those in limb muscle may be, however, due to the fact that the tumour growing in the brain kills the animal before a sufficiently intense immune reaction develops. That is, the comparison may not be quite fair as the anatomical difference may simulate an immunological privilege.

Histological findings in normal animals showed the presence of lymphocytes in the brain tissue, and these cells could have participated in the immune reaction evoked by injected tumour cells. In the proximity of tumour cells, infiltrates of lymphocytes were observed in the perivascular spaces. The immune reactions in the brain were demonstrated in the experiments of Šterzl and Lodin[6] in which the administration of antigen to the brain led to marked antibody formation by the immigrating cells localised in the brain. Thus, it seems that the vascularisation of the brain is sufficient to mediate the afferent and efferent arcs of the immunological reaction. Consistent with this notion are the speculations of Tilney and Gowans[7] who posed the question "if kidneys can sensitise their hosts by way of the blood, why cannot fully vascularised grafts in immunologically privileged sites do the same?" The vascularisation itself has an important role in the survival of the tissue implants in the brain[5,8]. But it is difficult to explain the long-term survival of allogeneic normal or tumour tissues, as observed by some investigators (see refs 1 and 2 for reviews). The avascularity of the implants might be the cause. Although the concept of the brain as an immunologically privileged site is still, to some extent, in dispute, the data reported here clearly show that after tumour inoculation the basic immunological reactions are carried out in the brain.

Table 2 The mortality range of allogeneic tolerant and syngeneic rats following inoculation of tumour cells into the brain

Recipients	No. of inoculated tumour cells 5×10^3	5×10^4	10^6
	Deaths on days		
Allogeneic tolerant	17–21	12–16	6–10
Syngeneic untreated	17–21	NT*	6–9

*NT, not tested.

Macrophages isolated from regressing Moloney sarcomas are more cytotoxic than those recovered from progressing sarcomas

THERE is increasing evidence that many tumours contain appreciable numbers of macrophages[1–3], and that these inflammatory cells can be cytotoxic for various neoplastic cells *in vitro*[4,5]. Thus at first it seems paradoxical that many tumours are progressive and lethal in spite of a high content of macrophages. But to kill a malignant cell, these inflammatory cells must be brought to an ill-defined state of 'activation'[6,7]. It is therefore conceivable that the macrophages in progressing tumours are less activated, and thus less cytotoxic, than those in spontaneously regressing neoplasms. To test this hypothesis we isolated macrophages from either regressing or progressing Moloney sarcomas and tested them *in vitro* for their capacity to release chromium-51 (^{51}Cr) from prelabelled target cells. The former were usually significantly more cytotoxic than the latter.

At the times of collection (7–13 d after inoculation) regressing tumours (regressors) were 0.3–0.5 cm in diameter, firm and somewhat difficult to distinguish from adjacent normal skeletal muscle. By contrast, progressing tumours (progressors) were 1–2 cm in diameter, soft and friable and contained no grossly identifiable muscle. There were small foci of recent haemorrhage in the centres of the larger tumours. Progressors, left to run their course, kill the host after metastasising to the lung[8,9], while regressors are rejected completely, usually by the fourth week after inoculation[3,8]. Regression is attended by an extensive mononuclear inflammatory response[8,10], shown in tumour disaggregation studies to consist principally of T lymphocytes and macrophages[3]. Both these inflammatory cell types are also found associated with progressors, but unlike regressing sarcomas, inflammatory cells do not penetrate beyond the peripheries of progressing neoplasms.

Tumours were disaggregated as before[11], and macrophage monolayers were established from the resultant cell suspensions[12]. Macrophages in monolayers were counted in Giemsa-stained monolayers after exposure to zymosan particles. As measured by release of ^{51}Cr (details in legend for Table 1), at a density of 1,500 mm^{-2}, macrophages recovered from regressing Moloney sarcomas killed both the P815 mastocytoma and SV40-transformed 3T3 target cells (Table 1), albeit with different efficiencies (probably reflecting differences in target cell susceptibility). By contrast, neither target cell was affected by macrophages collected from progressors. Similar results at this macrophage density have been obtained in three experiments.

The density of macrophages in monolayers is of critical importance in demonstrating their cytotoxicity. Several groups have shown, for example, that maximal killing by these cells is not obtained unless monolayers are confluent, or nearly so. Doe and Henson (unpublished results) have investigated this aspect of macrophage-mediated cytotoxicity in detail, using the basic assay system described here. When thioglycollate broth-induced peritoneal macrophages were activated by bacterial lipopolysaccharide, Doe and Hensen obtained no measurable cytotoxicity at monolayer densities of <3,000 mm^{-2}, while maximal effects (that is, >80% specific ^{51}Cr release) were obtained at macrophage densities of 5,000 mm^{-2} or more. In view of these findings it is clear that the experiments we have described, where monolayers were 50–60% confluent, did not distinguish whether progressor macrophages were absolutely unable to cause ^{51}Cr release or, rather, that they were simply diminished in their cytotoxic capabilities compared with regressor macrophages. We therefore addressed this point by establishing, for regressors and progressors, a series of monolayers of increasing macrophage density (details in legend for Fig. 1). Similar results were obtained in approximately 80% of all such experiments (postinoculation days 7–13), suggesting that progressor macrophages can kill, but that their relative cytotoxicity is much less than that of macrophages recovered from regressors. There was some variation, however, for occasionally (3 per 14 experiments) progressor macrophages gave a level of killing nearly as high as or, in one case, higher than that obtained using regressor macrophages. In contrast to the small amount of killing usually obtained with progressor macrophages, such results were obtained sporadically and were not reproducible. The cause of such variation may be technical or stem from some undefined variable associated with the tumour system.

Table 1 Cytotoxicity of macrophages recovered from regressors or progressors

Target cell	Source of macrophages	c.p.m. in supernates of triplicate cultures (mean ± s.d.)	% Corrected ^{51}Cr release
P815 mastocytoma	None	2,152±11	—
	Progressor	2,163±65	0.2
	Regressor	4,127±35	32.0*
SV40-transformed 3T3 cell	None	1,808±14	—
	Progressor	1,798±56	−0.2
	Regressor	2,247±92	10.0*

Regressing or progressing Moloney sarcomas were induced in 6–8-week-old, male, BALB/c mice by intramuscular injection of either 5×10^3 or 10^6 cultured MSC cells, respectively[3,8]. Tumours collected 13 d later were disaggregated using a stirred mixture of trypsin, collagenase (each 0.1 mg ml^{-1}) and DNAse (0.025 mg ml^{-1}) (ref. 11). Macrophages in resultant cell suspensions were plated in 16-mm diameter, flat bottomed wells of plastic tissue culture trays (Linbro). Monolayers (50–60% confluent) containing 3×10^5 cells per well (1,500 per mm^2) (determined by cell counting using an inverted microscope equipped with a gridded ocular of known area) were obtained by brief exposure of each well twice to 2.5×10^6 cells from the crude suspension in 0.5 ml HEPES-buffered (15 mM) minimum essential tissue culture medium (HMEM) containing 10% foetal bovine serum (FBS). Five minutes after each seeding plates were agitated and all non-adherent cells were washed away after a total of 10 min. Ninety per cent of the adherent cells from both regressors and progressors were macrophages, as determined by microscopic examination of representative, Giemsa-stained monolayers treated and untreated with zymosan particles. The principal contaminants were tumour cells and polymorphonuclear leukocytes. Target cells antigenically unrelated to MSC cells, and therefore insusceptible to killing by the rare T lymphocyte which may have contaminated effector cell populations, were labelled for 1 h in HMEM+10% FBS containing sodium ^{51}chromate (250 μCi ml^{-1}, Amersham/Searle, Arlington Heights, Illinois; specific activity 200 mCi mg^{-1}). After washing, targets were allowed to stand at 37 °C for 2 h (with agitation at 30-min intervals), counted, resuspended in HMEM+30% FBS and added to wells (10^5 each; macrophage-to-target cell ratio 3:1). After incubation at 37 °C for 17 h, half of each culture supernate, collected by centrifugation, was assayed for radioactivity in an automatic gamma scintillation spectrometer. Percentage corrected ^{51}Cr release was computed using the formula ((experimental ^{51}Cr release − spontaneous ^{51}Cr release) ÷ (freeze-thaw ^{51}Cr release − spontaneous ^{51}Cr release)) × 100. Negative values indicate that release in experimental cultures was less than spontaneous release. Rates of spontaneous ^{51}Cr loss by P815 and SV40-transformed 3T3 cells were 1.5% and 1.7% per h, respectively.

*As determined by Student's *t* test, the differences in cytotoxicity between regressor and progressor macrophages are significant at the <0.01 (SV40 3T3) and <0.001 (P815) levels.

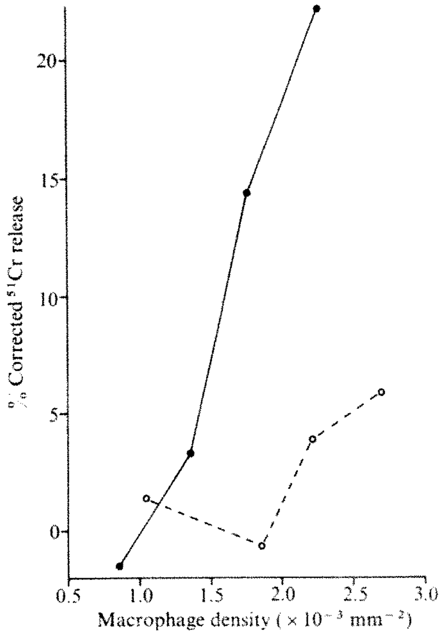

Fig. 1 Cell suspensions were prepared from either regressing (●) or progressing (○) Moloney sarcomas (postinoculation day 8) and plated as described under Table 1 and in ref. 12. Numbers of macrophages were increased by repeated exposures of Linbro wells (200 mm^2) to the crude cell suspension. The lowest density was obtained by a single exposure of 5 min, the second by one exposure of 10-min, the third by two 10-min periods, and the highest by three 10 min incubations. The wells were washed after each exposure. Specific ^{51}Cr release was assayed as described under Table 1.

Thus it seems that macrophages recovered from regressing Moloney sarcomas generally are more cytotoxic than those obtained from progressing neoplasms of the same type. There is precedent for this finding in the work of

Fidler[6] and G. Miller and J. Feldman (personal communication). In both cases peritoneal macrophages induced by injection of thioglycollate broth were cytotoxic if the animal from which they came had been pre-immunised against the tumour target cell used, but were unable to kill or were greatly diminished in this capacity, if collected from an animal which carried a progressing tumour induced by the same target cell. Fidler's work further suggested that the observed inability to kill was not an innate deficiency of the macrophage, but was due to lack of macrophage activation by soluble lymphocyte mediators. One possible explanation for the diminished cytotoxicity exhibited by progressor macrophages therefore is inadequate activation of these cells by intratumoral lymphocytes. Indirect support for this hypothesis is found in the recent demonstration that, in at least one regard (direct mediation of cytotoxicity), T lymphocytes recovered from large progressing Moloney sarcomas were functionally inactive[13]. Direct testing of the macrophage activating potential of progressor T lymphocytes is in progress.

This work was supported by USPHS (contract CB44001 and research grant CA17720). S.W.R. is the recipient of a Research Career Development Award from the NCI. We thank Dr G. Y. Gillespie for advice and criticism, Mr Ronald Hoskins and Ms Marty Fujita for technical assistance, and Mrs Lois Rude for preparing the manuscript.

Aspartic acid racemisation in the human lens during ageing and in cataract formation

D-ASPARTIC acid has been shown to accumulate with age in human tooth enamel[1] and dentine[2] at a rate of about 0.1% yr^{-1}. We have predicted that racemisation should take place in any metabolically stable protein in long-lived mammals and that, as a consequence of racemisation, these proteins will have altered conformations which would probably produce changes in their biological activities or chemical properties[3]. We have extended these studies to soft tissue proteins, in particular those in the human lens. The proteins in the central portion of the lens are among the most stable in the human body[4]. Numerous changes in the properties of the lens proteins occur with age and cataract formation—denaturation[5], increasing pigmentation[6], cross linking[5,6] insolubility[6–9], and fluorescence[10]. Pirie[11] has suggested that' physicochemical processes may be responsible for these changes. We report here the results of D/L enantiomeric analyses of normal human lenses and cataracts: aspartic acid racemisation was seen during ageing and cataract formation.

Human lenses were obtained from Eye Bank collections or after surgical extraction at the Duke University Medical Center. Cataracts were graded according to the colour classification of Pirie[6]: group I, pale yellow lens; group II, pale cortex with visible nucleus; group III, pale cortex with hazel brown nucleus; group IV, pale cortex with deep brown nucleus. The central 15% by weight of each lens was removed by the method of Spector *et al.*[10]; these samples will be referred to as the central nuclei. A freshly extracted cataract lens from a 76-yr-old individual was sectioned as above. Then two additional samples were taken from the remainder of the lens, one representing the inner cortex and a second from the peripheral cortex. All lens samples were stored frozen.

The samples were processed using procedures described elsewhere[12,13]. Measurements of D/L aspartic acid ratios were performed on a Beckman-Spinco Model 118 automatic amino acid analyser, using the diastereomeric dipeptide technique[14]. The D/L enantiomeric ratios for glutamic acid, proline, alanine, phenylalanine, and leucine were determined by gas chromatography. The *N*-trifluoroacetyl-L-prolyl peptide methyl esters were synthesised, and separation was performed by gas chromatography (Hewlett-Packard Model 5711A with flame ionisation detector; 20-foot glass column packed with 8% SP 2250 coated on Chromosorb W-AW-DMCS solid support[15]).

The D/L aspartic acid analyses for the central nucleus samples of 17 normal human lenses are plotted in Fig. 1. The line in Fig. 1 represents a least squares fit to the normal lens data, and the equation for this line is

$$\ln\left(\frac{1+\text{D/L}}{1-\text{D/L}}\right) = (2.50\,(\pm 0.29)\times 10^{-3}\text{yr}^{-1})(t+0.112) \quad (1)$$

where t is the age of the individual. The data are presented in the form of the reversible first order rate equation[16], rather than the irreversible equation used for the enamel and dentine results[1,2], because D-aspartic acid is present in sufficient concentrations in the lenses to make the use of the irreversible first order rate equation invalid. The slope in equation (1) corresponds to $2\,k_{\text{asp}}$. Thus, in the lens nucleus, $k_{\text{asp}} = 1.25\times 10^{-3}\,\text{yr}^{-1}$. The correlation coefficient (r) for the lens results is 0.912.

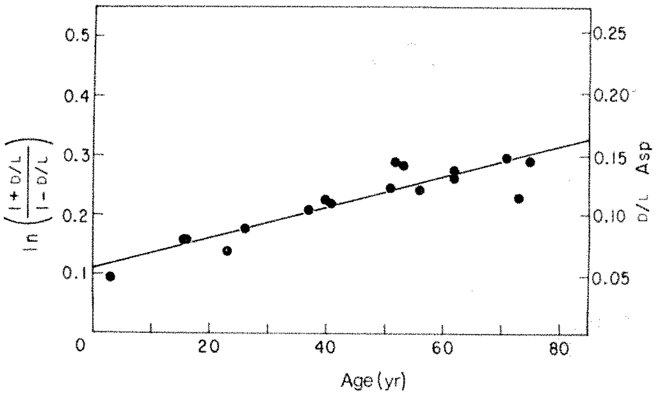

Fig. 1 Analysis of D/L-aspartic acid contents of central nucleus samples of 17 normal human lenses.

The y-intercept, 0.112, is equivalent to a D/L ratio of 0.056. This ratio is higher than the enamel[1] (0.033) and dentine[2] (0.017) $t = 0$ values. A possible explanation for this difference is that the primary structures of proteins may influence the amount of acid-catalysed racemisation which occurs during the hydrolysis step[14].

Since the proteins in the central nucleus are thought to be 'older' than the proteins in the peripheral regions of the lens, the D/L-aspartic acid ratios should be higher in the nucleus than in the cortex in samples from the same lens. The D/L ratios obtained for the nucleus, inner cortex, and peripheral cortex of the 76-yr-old cataract are 0.171, 0.167, and 0.047, respectively. Only the peripheral cortex shows evidence of recent protein synthesis. The peripheral cortex result is identical to the D/L ratio from the 3-yr-old lens nucleus, that is, 0.047, and may provide a closer approximation to the $t = 0$ value for human lens proteins than the extrapolated value of 0.056.

Our studies of racemisation rates in teeth[1,2] led us to propose that D/L-aspartic acid analyses can be used as a biochronological tool to estimate the ages of long-lived mammals. Racemisation in the lens nucleus can be used in a similar manner. There are several advantages to working with lenses rather than teeth for mammalian age determinations. (1) Temperature is probably higher and more constant. (2) Teeth of certain mammals, such as cetaceans, have a rather complex pattern of development in which dentine growth layers are laid down well into adulthood[17]. (3) Normal tooth attrition makes sampling from old animals difficult. (4) The faster k_{asp} in lenses permits young ages to be calculated more accurately.

The extent of aspartic acid racemisation in the central nuclei of 13 group I and II cataracts was determined, and a least squares fit of these data yielded $k_{asp} = 1.29 \times 10^{-3}$ yr^{-1} ($r = 0.875$), which is indistinguishable from the rate in normal lenses. This is particularly interesting since the cataracts included subcapsular, nuclear, and cortical types associated with different aetiologies or disease states (trauma, diabetes, hypertension, glaucoma, Parkinson's disease and so on). Thus, despite the development of these types of cataracts, the racemisation rate is identical to that observed in the lens nucleus during the normal ageing process.

The brunnescent group IV cataracts listed in Table 1, on the other hand, have a much greater degree of aspartic acid racemisation than we have observed in any stable human proteins. These cataracts have D/L-Asp ratios 58–97% higher than either the normal lenses or group I and II cataracts of similar ages. One yellow cataract of unknown age also had a very high D/L ratio of 0.265, which is equivalent to the brunnescent lens values, while a group III cataract (76 yr. D/L Asp = 0.171) falls within the range of the yellow cataracts. Therefore, enhanced aspartic acid racemisation is strongly but not invariably associated with the development of brown pigment during cataract maturation.

Table 1 Extent of aspartic acid racemisation in brunnescent cataracts

*The expected ratios were calculated from equation (1) using the age of each individual.

Gas chromatographic analyses were performed on two normal (3- and 75-yr-old), seven yellow, and three group IV lenses to determine the D/L enantiomeric ratios for alanine, glutamic acid, proline, phenylalanine and leucine. No racemisation of these amino acids was observed in any of the lenses. (The expected ratios[18] are at the limits of detection by this technique, however). Thus, only aspartyl residues are racemising to a measurable extent in the nuclear proteins of these lenses, which is the expected result[18]. Also, our results suggest that only aspartic acid exhibits an accelerated rate of racemisation in the brown cataract lenses.

If aspartic acid racemisation has a role in biological processes, including ageing, the reaction must occur in a variety of tissues. D-aspartyl residues have been shown to accumulate in normal lens nuclear proteins at a rate of 1.25×10^{-3} yr^{-1} or 0.14% per year, and therefore aspartic acid racemisation should take place with age in any stable soft tissue protein in long-lived mammals.

The rate constant for the lens nucleus is about 1.5 times the rate observed in tooth enamel and dentine. Although these rate constants fall within two s.d. of each other, several variables could be contributing to the difference in rates. The most obvious explanation is that the temperature of the lens is probably more constant and slightly higher than that of teeth, leading to a more rapid racemisation rate. Alternatively, the different protein environments in calcified and non-calcified tissue could explain the differences. The accelerated aspartic acid racemisation rate associated with brunnescent cataracts cannot be explained by the above factors. Among the possible mechanisms which could give rise to an accelerated rate during cataract maturation are change in the pK_a of the β-carboxyl group due to alteration in the microenvironment within the protein[19] and chelation of the β-carboxyl group by trace metals[18].

We have suggested that D-aspartyl residues should alter the conformation of a protein and that these effects will become more pronounced as the D-enantiomer accumulates with age[3]. A number of studies indicate that structural changes occur in lens proteins with age and in cataracts. The proportion of water-insoluble protein increases with age[8,9], and the increase is even more marked in cataracts[6,8]. The water-insoluble residue can be refractionated with concentrated urea. The urea-insoluble portion is greater in cataracts[6] and occurs primarily in the lens nucleus[7]. The proteins in cataractous lenses have an increased number of exposed thiol groups and a greater susceptibility to tryptic digestion, which suggests that conformational changes are taking place during cataractogenesis[5]. Cataracts show evidence of more disulphide[20,21] and non-disulphide[7] covalent cross links than do normal lenses, and the cross links increase during cataract maturation. It is possible that aspartic acid racemisation may actually be induced by structural changes in the lens proteins initiated by other factor(s). But, the above observations are also consistent with the predicted consequences of the racemisation of aspartyl residues.

We do not know whether the accelerated rate of racemisation of aspartic acid contributes to the development of brunnescent cataracts or whether during cataract formation the aspartyl residues become more susceptible to racemisation. Since the percentage of urea-insoluble protein increases more than fourfold between yellow and group IV cataracts[22], protein alteration seems to coincide with the increase in racemisation rate.

Regardless of the actual mechanism responsible for the accelerated rate of aspartic acid racemisation in cataract maturation, this chemical alteration provides important information on processes taking place in the human lens during the development of a pathological condition. Elucidation of this mechanism may provide new insights into the process of cataract maturation.

A role of selenium against methylmercury toxicity

SINCE Parizek *et al.*[1] reported that administration of selenite clearly decreased toxicity of mercuric chloride, there have been many studies on the mechanisms responsible for the interrelationship between selenium and inorganic or organic mercury. Almost all have shown that inorganic selenium, especially selenite, prevents growth inhibition as well as mortality and neurotoxicity due to methylmercury given simultaneously in the diet of Japanese quail[2-4] and rats[5-8]. Protective effects of selenium against methylmercury toxicity do not involve mercury absorption through intestines[9] or excretion in the urine and faeces[6]. Selenite does not increase the rate of breakdown of methylmercury[7], and thionein does not have a significant role in the detoxification of methylmercury[3], but presumably, the form of methylmercury is modified in some way by selenium. We present here evidence that selenite can release methylmercury from its linkage with proteins and thereby influence its tissue distribution.

The association constants of methylmercury for sulphur ligands of the sulphydryl group of proteins are extremely large[10]. But methylmercury in animal tissues can be separated from Hg–S linkage by hydrochloric acid (1 M or 2 M) and extracted with benzene, then analysed, using a gas chromatograph with an electron capture detector[11]. Methylmercury extracted with benzene in acid conditions is defined as total methylmercury, methylmercury extracted in neutral conditions as free methylmercury and the difference between them as bound methylmercury.

Selenium compounds in phosphate buffer (*p*H 7.4) were added to methylmercury and defibrinated human blood and methylmercury was extracted with benzene after 2 h of incubation. Selenite showed a surprisingly high ability to release methylmercury from blood proteins and the effect of selenate is one-tenth that of selenite (Fig. 1). Na_2SO_4, Na_2SO_3, $Na_2H_2TeO_6$ and Na_2TeO_3 were not effective in inducing release of methylmercury.

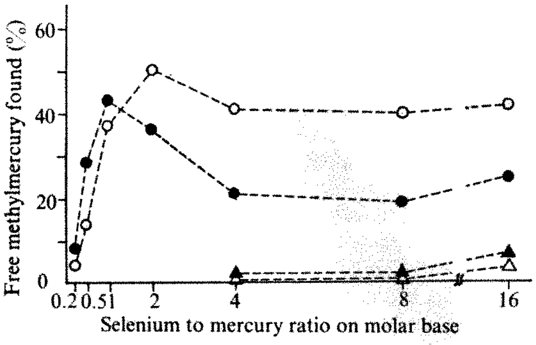

Fig. 1 Release of methylmercury from human blood by Na_2SeO_3 or Na_2SeO_4. A mixture of 0.5 ml of defibrinated blood, 5 nmol methylmercury chloride and selenite or selenate in 5 ml of phosphate buffer (*p*H 7.4) was incubated for 2 h and free methylmercury was extracted in 2 ml of benzene. The benzene layer was analysed by a gas chromatograph with electron capture detector of ^{63}Ni in the following conditions: 3 mm × 1 m glass column of Thermon 1000 on Chromosorb W at 80 ml min^{-1} of N_2 flow rate and 180 °C. ○, Na_2SeO_3 at 37 °C incubation temperature; ●, at 20 °C; △, Na_2SeO_4 at 37 °C and ▲, at 20 C°.

Addition of selenite and blood was effective in releasing methylmercury bound to bovine serum albumin, human serum, cysteine and glutathione. Addition of serum had no effect, but red blood cells effectively induced methylmercury release and did not lose effectiveness even if haemolysed by water or washed by benzene; however, they lost this ability when coagulated by heating or denatured (for example by alcohol).

Red blood cells and liver, kidney and brain homogenates from rats (Fig. 2) and mice, and muscle homogenates of raw tuna were also able to release methylmercury in conjunction with selenite. The amounts of free methylmercury released by active agents were proportionate to incubation time, amounts of biological sample, and incubation temperature. The larger the sample size and the higher the temperature, the sooner the maximum point tended to be reached. This occurred in both homogeneous and heterogeneous systems, and also in all cell fractions of mitochondria, microsome and supernatant fractions at 100,000*g*. The optimal *p*H was about 6.5 in conditions detailed in Fig. 1, with different phosphate buffers. The ratio of Se to Hg in the benzene layer was not always constant. The value of methylmercury at molar base was

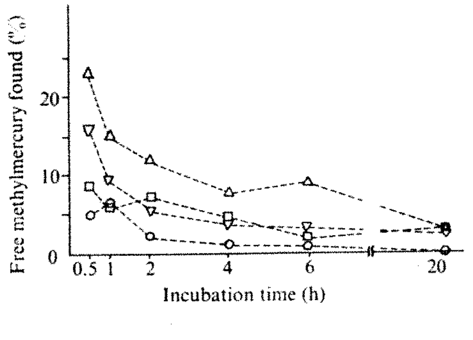

Fig. 2 Release of methylmercury from albumin by tissue homogenates and Na_2SeO_3. Methylmercury chloride (50 nmol) and 2 ml of 1% egg albumin were mixed and 50 nmol of sodium selenite and 1 ml of rat tissue or blood homogenate (each homogenate composed of one third tissue or blood and two thirds phosphate buffer) were added. Enough phosphate buffer was added to bring the total volume to 50 ml, and the mixture was incubated at 37 °C. Free methylmercury was separated from 5-ml aliquots with 2 ml benzene. □, Liver; ▽, kidney; △, brain, and ○, blood.

Table 1 The effects of sodium selenite on the *in vivo* release and tissue distribution of methylmercury

TM, total methylmercury, and FM, free methylmercury. Values in FM(%) columns are the extreme ranges; figures in parentheses show the median. Group I received 100 μg of methylmercury chloride s.c. and, were killed after 1 week. Group II received 69 μg of sodium selenite i.p., 15 h before killing, which occured 1 week after methylmercury. Group III received 69 μg of selenite i.v., 30 min before killing, which occurred 1 week after methylmercury.

$^*P = 0.05$.

$^{**}P = 0.01$.

two or more times higher than that of Se estimated by flameless atomic absorption. Moreover, methylmercury from the benzene phase could be removed by cysteine solution, but Se remained largely (about 80%) in the benzene layer. This suggests that selenium may not have been associated with methylmercury. Selenite had a similar effect on methylmercury in the organs of mice treated with methylmercury *in vivo*. There was no evidence to indicate that methylmercury added was changed to dimethylmercury or to inorganic mercury.

In the *in vivo* experiments, dd-strain female mice weighing 25 g were given 100 μg methylmercury subcutaneously. About 1 week later sodium selenite, 69 μg was injected intravenously (i.v.) into the tail vein or intraperitoneally. After the selenite injection, blood samples were collected by heart puncture, and livers (detailed in Table 1), kidneys and brains removed. Blood and tissue homogenates were extracted by benzene both in the absence and presence of hydrochloric acid. After i.v. injection of selenite, free methylmercury was found in blood, liver and kidney but none in brain (Table 1). Total methylmercury content in kidney was also clearly decreased by selenite, but there were no changes in other organs.

It seems reasonable to conclude that the shift in the tissue distribution of methylmercury is a natural consequence of the liberation of methylmercury from sulphydryl bonds.

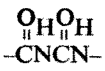
Intermolecular association and geometrical shape as two factors controlling chemical reactions

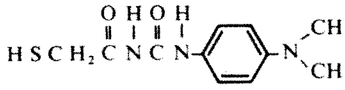
BIOLOGICAL phenomena are highly specific[1–4] and much effort has been devoted to establishing the relationship between biological activity and molecular shape. We report here the sharp dependence of selectivity in the oxidation of a pair of thiols on their structures or on environment, the mode of each dependence of selectivity being controlled dominantly by their tendency towards intermolecular association.

Two types of model systems were used. One pair of reactants can associate through intermolecular hydrogen bonding (associating system, system A) and the other pair cannot (non-associating system, system N). The model compounds (I and II) for system A are composed of three regions—the reaction site (SH group) where oxidation takes place, the binding site

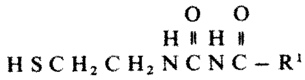


$$-\overset{O}{\overset{\|}{C}}\overset{H}{N}\overset{O}{\overset{\|}{C}}\overset{H}{N}-$$

an acylurea bond that can participate in intermolecular hydrogen bonding[5], and the recognition site ($-C_6H_4N(CH_3)_2$ or R^1) that may further participate in the discrimination. A pair of simple thiols, ethyl thioglycolate (III)



I



$$HSCH_2CH_2\overset{H}{N}\overset{O}{\overset{\|}{C}}\overset{H}{N}\overset{O}{\overset{\|}{C}}-R^1$$

II

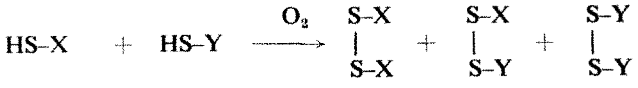
$HSCH_2CO_2C_2H_5$

III

$HS{-}R^2$

IV

and alkanethiol (IV, $R^2 = (CH_2)_kCH(CH_3)_2$), were used as the model compounds for system N. A 1:1 mixture of I and II (or of III and IV), on treatment with oxygen, gave one unsymmetrical and two symmetrical disulphides. The selectivity factor (R) in this oxidation (an indication of recognition of II by I—or of IV by III), is represented by the ratio ($V/VI = R$) of unsymmetrical disulphide (V) to symmetrical disulphide (VI) obtained from I or III.



I or III   II or IV   VI   V

Oxidation of a mixture of methanethiol and ethanethiol is known to yield the three disulphides in a 1:2:1 ratio[6]. This was also the case with oxidation of system N in 80% aqueous acetonitrile at 35 °C: the product ratio (R) was 2.1 in two cases ($k = 1$ and 2, Fig. 1). In contrast, quite different results were obtained with system A. When a series of branched alkyl groups ($(CH_2)_mCH(CH_3)_2$) were used as R^1, selectivity showed a maximum ($R = 21.2$, $V = 87\%$) at $m = 2$. Such a remarkable dependence of selectivity on the substituent R^1, however, was not observed for system A where a series of straight-chain alkyl groups ($(CH_2)_nCH_3$) were used as R^1:

the product ratio (*R*) changed slightly from 0.3 to 0.5 except for the case $n = 2$. The data in Fig. 1 suggest the importance of intermolecular association in controlling chemical reactions through small changes in the structures of reacting molecules.

Figure 2*a* illustrates the plots of *R* at 35 °C against dielectric constants (ε), a measure of polarity of solvents. Figure 2*a* shows that with the associating system having the isopentyl group as R^1 in II (system A_a), selectivity decreased in going from 80% to 90% and 70% aqueous acetonitrile and from 80% acetonitrile to 80% dioxane and 80% *N,N*-dimethylformamide (DMF) with the maximum at 80% acetonitrile ($\varepsilon = 42.6$). The marked dependence of selectivity on ε led us to examine whether the thiol I or II associates in benzene or in acetonitrile—using a differential vapour pressure method. The degree of association (*f*), obtained by dividing the stoichiometric mole fraction of the solute by the effective mole fraction of the solute, was 1.31, 1.80, and 1.77 in benzene at 36 °C for I (0.01 M), II_a (0.04 M, $R^1 = isoC_5H_{11}$), and II_b (0.04 M, $R^1 = n\text{-}C_5H_{11}$), respectively. In contrast, in acetonitrile *f* was reduced to 1.04, 1.08, and 1.03 at 36 °C for I (0.02 M), II_a (0.04 M), and II_b (0.04 M), respectively. These data clearly indicate that *f* is reduced with increasing solvent polarity[7]. Accordingly, it is suggested that moderately weak association is essential for effective recognition between molecules, strong association being not essential. When the associating system contained the *n*-pentyl group as R^1 (system A_b), however, *R* had a minimum, though selectivity in this case was far less sensitive to ε than that with system A_a. In sharp contrast, with the non-associating system with the isopentyl group as R^2 in IV (system N_a) *R* showed a very slight variation from 2.5 to 1.8. This control experiment demonstrates that in the absence of intermolecular association, the three disulphides are formed in a nearly statistical ratio.

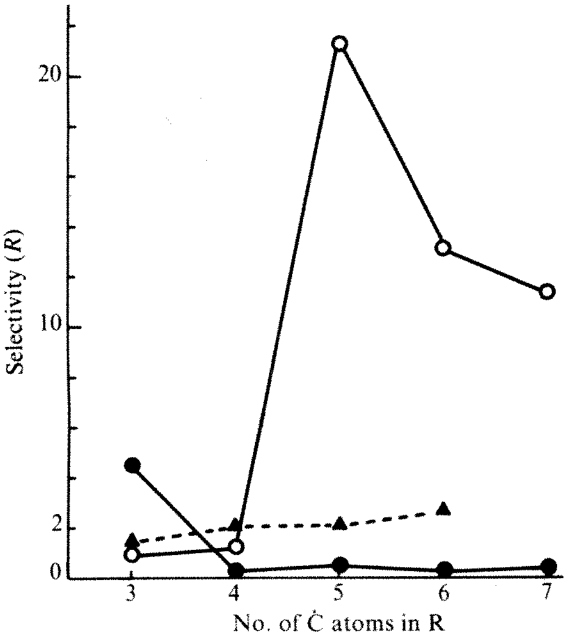


Fig. 1 Dependence of selectivity (*R*) in oxidation of a pair of the thiols (I and II or III and IV) on the structures of R^1 or of R^2. The two thiols (0.5 mmol each) were allowed to react with O_2 in 12.5 ml of 80% aqueous acetonitrile (v/v) at 35 °C in the presence of Et_3N (5×10^{-2} mmol) as a catalyst. Satisfactory spectroscopic data were used to support the assignment of new compounds. When the oxidation was completed, yields of V and VI were determined exactly by the use of their absorption at 310 nm after separation by thin-layer chromatography for system A, and determined gravimetrically after separation by preparative thin-layer chromatography for system N. ○, System A (R^1, branched alkyl groups); ●, system A (R^1, straight-chain alkyl groups); ▲, system N (R^2, branched alkyl groups).

In system A_a a plot of selectivity in 80% acetonitrile against temperature showed a peak of maximum selectivity at 35° C (Fig. 2*b*). In system A_b, however, the pattern of temperature dependence did not correspond to that of solvent polarity—*R* changed progressively over a wide range (0.13—2.3).

Of particular interest is the concentration dependence of selectivity with system A_a in 80% dioxane at 35 °C, represented by a sigmoid-like curve similar to the substrate concentration–reaction rate profiles observed with allosteric enzymes (Fig. 2*c*). In the case of systems N_a and even A_b, however, *R* remained almost constant with concentration.

In considering the significance of intermolecular association, it should also be noted that the product ratio (*R*) approaches about 2, the statistically expected ratio, in all systems in conditions unfavourable for hydrogen bonding, that is, in a polar solvent (for example *N*-methylformamide, NMF), at a higher temperature (70 °C), or at a lower concentration (1×10^{-3} M). It is clear from the results described here that environment dependence of selectivity is very sharp only in the case of system A_a among the systems examined.

All the results obtained from system A can be said to represent kinetic control on the basis of the following observations. First, the product composition does not change as the reaction proceeds, as is evident from the fact that the yields of V and VI during the period of the oxidation are 6.3% and trace, 15% and about 0.7% ($R = 21$), 23% and 1.1% ($R = 20.9$), 43% and 2.0% ($R = 21.5$), respectively, for system A_a and 2.2% and 4.4% ($R = 0.50$), 4.8% and 9.4% ($R = 0.51$), 14% and 27% ($R = 0.52$), respectively, for system A_b. System A_a required 2.5 h for complete oxidation to give 87% V and 4.1% VI ($R = 21.2$), whereas system A_b required 3.5 h to give 20% V and 39% VI ($R = 0.51$). Second, a thiol–disulphide exchange reaction occurred slowly in 80% acetonitrile at 35 °C in the presence of a catalytic amount of triethylamine under argon. The yields of V and VI at the same reaction time as with the above oxidation were 24% and 22%, respectively, for system A_a ($R = 1.1$, reaction time = 2.5 h) and 3.9% and 40%, respectively, for system A_b ($R = 0.098$, reaction time = 3.5 h), indicating that the product distribution in the exchange reaction differs entirely from that in the oxidation. The disulphide–disulphide exchange reaction did not take place to any appreciable extent in 80% acetonitrile at 35 °C in the presence of a catalytic amount of both I and triethylamine under argon[8].

System A was heterogeneous in some cases. However, the product ratio could not be ascribed to differential solubilities of the thiols and the product disulphides for the following reasons. First, the experiments on concentration dependence shown in Fig. 2*c* were carried out in completely homogeneous conditions, but the selectivity showed a sigmoid-like curve in the case of system A_a. Second, in 80% dioxane, 80% DMF, and NMF system A_a was also completely homogeneous at 35 °C during the oxidation, but *R* varied markedly from 14 to 1.9 (Fig. 2*a*). Third, in 80% acetonitrile a pair of the thiols I and II_a were completely soluble in the 25–70 °C range, the thiols I and II_b being also soluble at 35 and 70 °C (Fig. 2*b*). Further, the unsymmetrical and symmetrical disulphides derived from I and II were very stable in the reaction conditions, the unsymmetrical disulphides being more soluble in ordinary solvents than the symmetrical disulphides. These findings show conclusively that the selectivity is neither controlled by solubility differences between the thiols and disulphides and between disulphides V and VI nor by whether the reaction is heterogeneous or homogeneous[9].

Although the detailed nature of the specific interactions between I and II has not yet been made clear, the following observation suggests the presence of such interactions in system A_a. Plots of *R* against the mole ratio of I and II_a showed a maximum rise of *R* in a 1:1 mixture of I and II_a, indicating that I and II_a seem to form 1:1 weak complexes with each other, but not to complex with themselves. This type of complex is apparently stabilised by such interactions as those between the

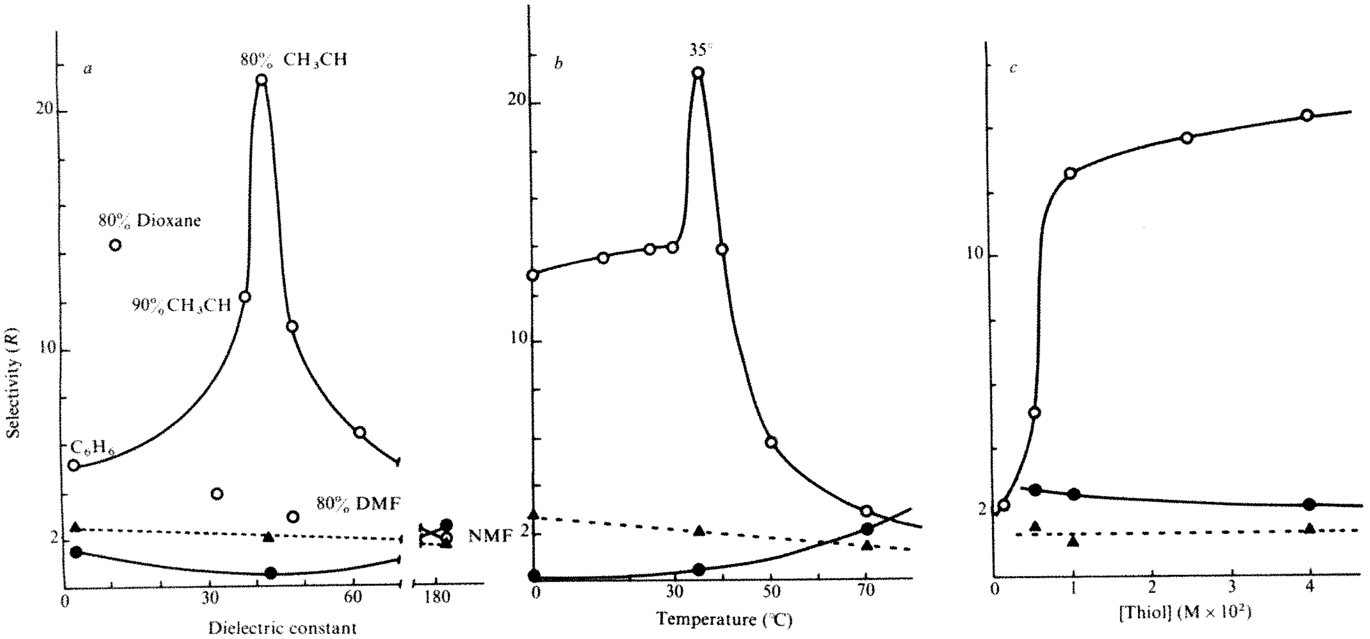

Fig. 2 Dependence of selectivity (R) in oxidation of a pair of the thiols (I and II or III and IV$_a$ (R^2 = isoC_2H_{11})). *a*, Dielectric constants of solvents (12.5 ml) at 35 °C; *b*, on reaction temperature in 12.5 ml of 80% acetonitrile, and *c*, on concentration of each thiol in 80% aqueous dioxane at 35 °C. The oxidations with O_2 were performed by using the same molar amounts of the thiols and Et_3N as described for Fig. 1. The series of solvents used to study solvent polarity dependence was (in order of increasing dielectric constant): benzene, 80% aqueous dioxane, methanol, 90% and 80% aqueous acetonitrile, 80% aqueous DMF, 70% and 50% aqueous acetonitrile, and NMF. ○, System A_a; ●, system A_b; △, system N_a.

aromatic ring in I and the branched alkyl group in II, in addition to intermolecular hydrogen bonding[10] between the two respective acylurea bonds in I and II. We conclude from our studies that both intermolecular association and geometrical shape are required for molecular recognition in chemical reactions.

Our results suggest that the use of appropriate model compounds which can associate and are of relatively low molecular weight should increase understanding of the problem of molecular recognition.

We thank Professor Teruaki Mukaiyama for encouragement and Dr Motohiro Nishio for reading the manuscript. The Matsunaga Science Foundation provided financial support.

Effects of cyclic AMP pulses on adenylate cyclase and the phosphodiesterase inhibitor of *D. discoideum*

STARVATION triggers the differentiation of *Dictyostelium discoideum* amoebae to aggregation competence. The differentiated cells orientate and migrate towards attracting centres, presumably consisting of amoebae which autonomously and rhythmically emit cyclic AMP as a chemotactic signal. Signals, emitted with a periodicity of 5–8 min (refs 1–3, 5), are presumably generated by rhythmic changes in adenylate cyclase activity[6], levels of which dramatically increase during the first few hours before the expression of aggregation competence[7,8]. Cellular responses to external cyclic AMP are probably mediated by plasma membrane receptors[9]. When stimulated by a pulse of cyclic AMP, amoebae amplify[10] and relay[1,5,10,11] the chemotactic signal, which results in a coordinated aggregation. The decay of the chemotactic signal is determined by the activity of the extracellular cyclic AMP phosphodiesterase[12,13] whose activity is modulated by an inhibitor excreted by cells during the early hours of starvation[14]. Cyclic AMP pulses have recently also been shown to regulate the differentiation of cells to aggregation competence[15]. To determine their mechanism of action, we examined the influence of applied cyclic AMP pulses on the two earliest biochemical events implicated in the control of cyclic AMP levels, the rise in adenylate cyclase activity and the appearance of the extracellular phosphodiesterase inhibitor. The results show that adenylate cyclase may exist in active or inactive forms. Applied cyclic AMP pulses seem to induce cell differentiation by activating the enzyme. They also are shown to repress the production of the phosphodiesterase inhibitor.

The changes in adenylate cyclase and the extracellular phosphodiesterase inhibitor which occurred when amoebae were starved in the presence or absence of cyclic AMP pulses are shown in Fig. 1. These changes are compared with the development of aggregation competence and the increases in cyclic AMP binding sites[9,16] and phosphodiesterase[16,17] which accompany it. In this experiment unpulsed amoebae were aggregation competent after 6–7 h of starvation, when they showed high levels of intracellular phosphodiesterase activity and cyclic AMP binding sites (Fig. 1*a*). When cells were pulsed with cyclic AMP, high levels of these two parameters were observed after 4.5–5 h of starvation, when they expressed aggregation competence. Assays of adenylate cyclase showed that the time course of enzyme induction was unaltered by cyclic AMP pulses: with pulsed and unpulsed cultures, activity first rose after 2 h of starvation and was maximal after approximately 5 h.

Determinations of the levels the extracellular phosphodiesterase inhibitor excreted by pulsed cells showed that they produced approximately 4% of the inhibitor produced by untreated cells (Fig. 1*b*). Incubation of amoebae in buffer containing 10^{-3} M cyclic AMP, delayed the appearance of the inhibitor by 1–2 h. Inhibitor was produced again when the added cyclic AMP had been hydrolysed by the extracellular phosphodiesterase (data not shown). The efficiency of 10^{-7} M cyclic AMP, when administered as pulses, in repressing inhibitor production may suggest that their effects are mediated by the increased cellular cyclic AMP levels obtained during signal amplification.

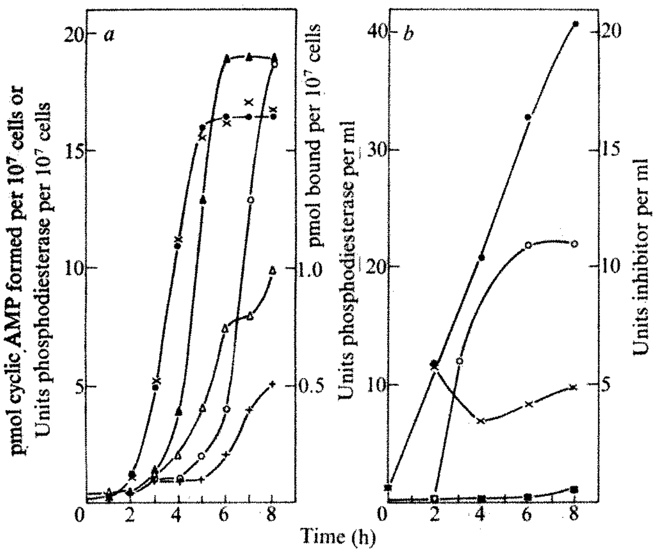

Fig. 1 Changes in adenylate cyclase, cyclic AMP binding sites, phosphodiesterase, and the phsophodiesterase inhibitor in cyclic AMP-pulsed and -unpulsed cells. Ax2 amoebae, harvested during exponential growth in HL-5 media[21], were washed twice with 17 mM phosphate buffer *p*H 6.2 and starved in that buffer as agitated suspensions[22] at a density of 10^7 cells ml^{-1}. Treatment of amoebae with 10^{-7} M cyclic AMP pulses was begun immediately after transfer of cells into buffer (t_0). The technique has been described in detail elsewhere[15]. Control cells were starved in the absence of applied pulses. At the indicated times, aliquots were taken and assayed for adenylate cyclase[7], cellular and extracellular phosphodiesterase activities[17] and the levels of cyclic AMP binding sites[23] and extracellular phosphodiesterase inhibitor[14]. Preparation of samples for inhibitor assays involves heating for 10 min at 80 °C (ref. 14). Although this treatment has been shown to result in a quantitative recovery of the inhibitor (independant of its interaction with the extracellular phosphodiesterase)[14], this was verified further for our experimental conditions where phosphodiesterase was present in large excess of inhibitor. Units of phosphodiesterase activity are defined as nmol cyclic AMP hydrolysed per min at 30 °C. The differentiation of cells to aggregation competence was followed by plating aliquots of cells on to Falcon tissue culture dishes at hourly intervals and observing cell morphology and formation of EDTA resistant cell contacts[22]. *a*, Adenylate cyclase of control cells (×) and of pulsed cells (●); cellular phosphodiesterase of control cells (○) and of pulsed cells (▲); cyclic AMP binding sites of control cells (+) and of pulsed cells (△). *b*, Extracellular phosphodiesterase of control cells (×) and of pulsed cells (●); phosphodiesterase inhibitor of control cells (○) and of pulsed cells(■).

Extracellular phosphodiesterase levels increased 4–5-fold during the time cells were stimulated by cyclic AMP pulses (Fig. 1*b*). This increase results from both a rise in enzyme production[17] and the decrease in the levels of the enzyme inhibitor. The dual control of cyclic AMP pulses on phosphodiesterase and its inhibitor assures the levels of extracellular phosphodiesterase required for cell differentiation (M.D. *et al.*, in preparation). Since amoebae feed on bacteria and therefore do not all begin to starve at the same time, the presence of the inhibitor during the early hours of starvation could assure that no aggregation occurs until the majority of the cell population produces the chemotactic signal. At that time, inhibitor production would be arrested and the phosphodiesterase induced.

The results described in Fig. 1 suggest that the rise in adenylate cyclase is not directly correlated with the expression of aggregation competence. This is further supported by the observation that unpulsed cell populations, which became aggregation competent after different time periods (5, 8 or 12 h), all increased their adenylate cyclase activities during the first few hours of starvation. In all these cases, applied cyclic AMP pulses did not alter the time course of the changes in adenylate cyclase but shortened the interval between the increase in this activity and the expression of aggregation competence and its related biochemical parameters. Cells may maximally increase their levels of adenylate cyclase during the first few hours of starvation but not display aggregation competence until many hours later because the enzymic activity assayed in cell lysates becomes functional in intact cells only after a delay. The following experiments support this hypothesis: Cells which became aggregation-competent within 5 h of starvation showed the periodic changes in light scattering correlated with changes in cyclic AMP synthesis and excretion[18] after 2–2.5 h. In contrast, cells which aggregated after 10–14 h did not show such behaviour during the first 6 h of starvation. Measurements of cyclic AMP produced by these cells showed that they did not synthesise cyclic AMP during the first 6 h of starvation. (Table 1, experiment 1). The levels of cyclic AMP synthesised by cells which were aggregation competent after 5–6 h of starvation are also presented (experiment 2).

Table 1 Cyclic AMP levels of late and early differentiating amoebae

	Cyclic AMP (pmol per 2 × 10^7 cells)	
Time of starvation (h)	Experiment 1	Experiment 2
2	0.17	3.5
4	0	4.0
5	.01	5.5
6	0	4.2

To initiate cell development, amoebae were washed twice with Volvic mineral water and resuspended in that water at a density of 10^7 cells ml^{-1}. No phosphate, which interferes with the assay for cyclic AMP, was added. The times at which cells became aggregation competent were the same as those which were starved in phosphate buffer (unpublished observations). Cells were starved as agitated suspensions[22] and at various times, 5 ml aliquots were added to 0.25 ml 100% TCA and immediately frozen in dry-ice ethanol. The procedure for sample preparation for cyclic AMP assays has been described[19]. Assays were performed using the protein kinase kit purchased from Amersham. In these experiments, cells collected from exponential growth (2–5 × 10^6 cells ml^{-1}) consistently became aggregation competent after 5 h of starvation. Therefore, to obtain cells which differentiated after a delay of 12–14 h, we harvested amoebae from early stationary phase cultures (experiment 1). It has been shown that such cells require longer periods of starvation in order to aggregate[24] but can be induced to differentiate within 8 h if pulsed with cyclic AMP[25]. It should be pointed out that the values for cyclic AMP levels produced by cells which become aggregation-competent after 5 h are minimum estimates because of the high levels of phosphodiesterase produced by differentiated cells.

Several arguments suggest that applied cyclic AMP pulses stimulate cell differentiation by activating adenylate cyclase rather than by merely replacing the endogenously produced chemotactic signal. Cells which aggregated after prolonged periods of starvation were, when pretreated with cyclic AMP pulses, induced to aggregate and therefore to produce autonomously the chemotactic signal after 6-7 h. An increase in cellular cyclic AMP levels resulting from signal amplification seems to mediate the induction of phosphodiesterase[17] and the repression of the enzyme inhibitor (described here) by cyclic AMP pulses. The stimulatory and inhibitory effects of various compounds on cell differentiation have been correlated with respective increases and decreases in cellular cyclic AMP[19] (P. Brachet and C.K., in preparation). Also Roos and Gerisch have recently shown that a transitory 2-fold stimulation of adenylate cyclase can be elicited by a pulse of cyclic AMP[20]. It is possible, however, that the activation of adenylate cyclase by external cyclic AMP pulses may not be the sole pathway by which pulses induce cell differentiation.

Significance of glucose oxidase in lignin degradation

GLUCOSE oxidase (EC 1.1.3.4) is commonly found in the stagnant substratum of lignocellulose degrading fungi accompanying phenol oxidases, cellulases and glucosidases[1–4], where the steady-state supply of available oxygen is undoubtedly very limited[5]. Yet oxidants other than oxygen have heretofore received little attention as potential co-substrates of this enzyme despite its poor affinity for oxygen[4,6]. Spectrophotometric studies reported here on the interaction of glucose oxidase with transitory quinone and free-radical lignol oxidation products demonstrate that these intermediates are capable of serving as co-substrates of the reduced flavoenzyme at low oxygen tensions. Evidence is presented which suggests that glucose oxidase operates in concert with laccase, the principal phenol oxidase of *Polyporous versicolor*[3,7], a typical 'white-rot' fungus noted for its capacity to degrade lignin[1,8–13], to maintain a laccase–glucose: quinone oxidoreductase cycle in the fungal substratum by which lignol substrates may become highly oxygenated and ultimately degraded.

Table 1 Laccase and glucose oxidase activities in culture extracts of *P. versicolor**

Substrate	mU ml^{-1} Laccase	Glucose oxidase
Chlorogenic acid	22–49	–
Glucose	–	68–164

*Extracellular enzyme activity in crude 10,000*g* supernatant. Cultures were grown on sterile semi-solid rye grass media[16] and cells collected 10–20 d after innoculation. Laccase and glucose oxidase were assayed polarographically[17] at 37 °C on a Gilson Oxygraph equipped with a water-jacketed Clark electrode cell. Routine assays were with 0.1–0.5 ml enzyme in 50 mM potassium acetate buffer, *p*H 5.0, and 10 µmol of substrate in a total volume of 1.8 ml. Enzyme units are expressed as µmol min^{-1} of substrate turned over at 37 °C and represent the range seen in assaying five separate colonies of *P. versicolor*.

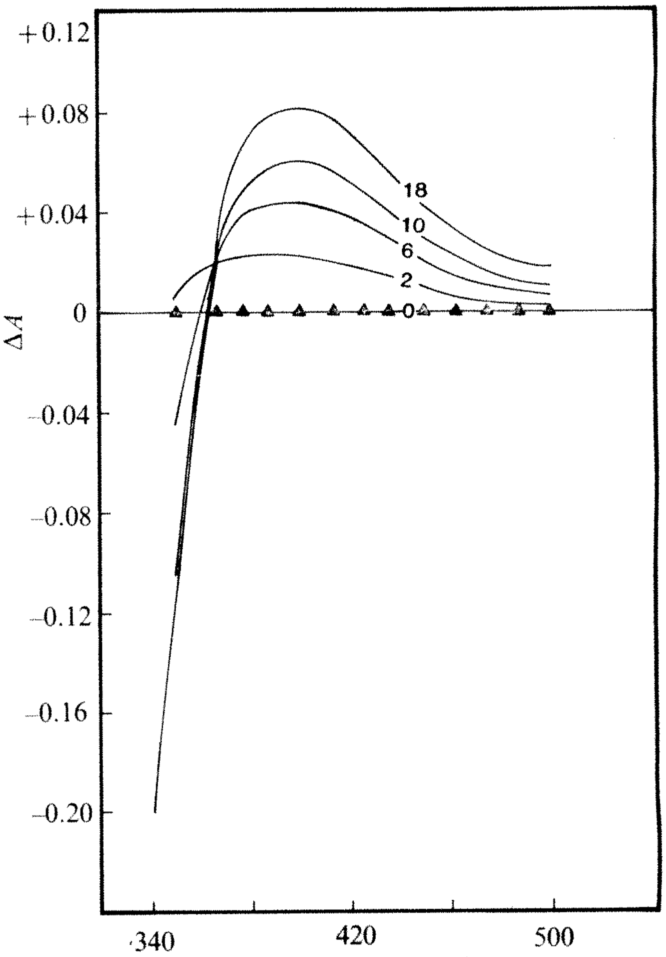

Fig. 1 Generation of quinoid intermediates *in situ* from chlorogenic acid by *P. versicolor* laccase. Sample and reference quartz cells contained 3.0 ml of 0.33 mM chlorogenic acid in 50 mM potassium acetate buffer, *p*H 5.0. At *t* = 0, 20 µl of stock enzyme (compare with Table 2) was added to the sample cell and the visible spectrum scanned on a Model 11 Carey spectrophotometer. Continuous scans were then made at 2, 6, 10 and 18 min after enzyme addition as indicated. Time-dependent difference spectra were plotted as the difference in absorption between the sample at time, *t*, following initiation of the reaction, and *t* = 0. —, Difference spectrum seen after 20 min when the same reaction was run with 0.15 mM sodium azide included in the assay mixture.

Five 'white-rot' fungi, *P. versicolor, P. abietnus, Poria sabicita, Phoriata adiposa* and *Formes fermentarius,* were chosen in initial screening trials for their capacity to produce extracellular phenol oxidases while growing on a semi-solid rye grass substratum supplemented with minimal salt media. Crude enzyme was recovered following filtration and centrifugation of initial slurries of the mycelial straw substrata prepared in 50 mM potassium acetate buffer, *p*H 5.0. Of the five fungi, *P. versicolor* grew most profusely on the semi-solid medium, and crude enzyme extracts of its substratum were especially rich in laccase and glucose oxidase activity (Table 1).

Dichlorophenol-indophenol (DCIP) was readily oxidised by enzyme mixtures exposed to air, as shown by a sharp blue shift in its adsorption maximum from 575 to 510 nm and a concomitant consumption of dissolved oxygen; it was not metabolised in solutions purged of oxygen and kept under nitrogen (Table 2). Addition of glucose to DCIP-enzyme mixtures under a nitrogen atmosphere brought about complete reduction of DCIP, however, and the readmission of air to these solutions resulted in the reappearance of the DCIP absorption spectrum. Interconversions between DCIP and its dihydro-form were induced through several cycles by appropriate adjustments of the oxygen tension, but continuous exposure of DCIP–enzyme mixtures to atmospheric oxygen resulted in irreversible losses of substrate no longer susceptible to further reductive cycles.

Model quinoid intermediates were also produced *in situ* by mixing laccase from test fungal extracts with the dilignol substrate, chlorogenic acid, as seen by a time-dependent, increased absorption maximum between 380 and 400 nm in the reaction mixture (Fig. 1). Excluding oxygen from the enzyme–substrate mixture, or blocking laccase activity by the addition of azide, prevented formation of this spectrum. These results link the appearance of the 380 nm absorption peak with *in situ* generation of quinoid intermediates.

Figure 2a demonstrates a dual requirement for both glucose oxidase and glucose in bringing about reduction of *in situ*-generated quinoid intermediates. Although most of the quinoid spectrum disappeared with glucose–glucose oxidase additions, there was a gradual accumulation of material less susceptible to reduction. Azide addition following initial generation of quinoid intermediates blocked further quinoid formation, and a slight decrease in the 380-nm absorption peak occurred thereafter (Fig. 2*b*). Subsequent additions of glucose and glucose oxidase to the azide treated samples caused only a slight further decrease in absorption. These latter results indicate a rapid turnover of quinoid intermediates. The residual, non-reduceable background absorption at 380 nm seems to coincide with a shift in the average absorption spectrum towards longer wave lengths (compare with Fig. 1) and probably reflects concomitant and irreversible structural rearrangements among transition state intermediates (for example, quinoid condensates, polymerisations) (ref. 13).

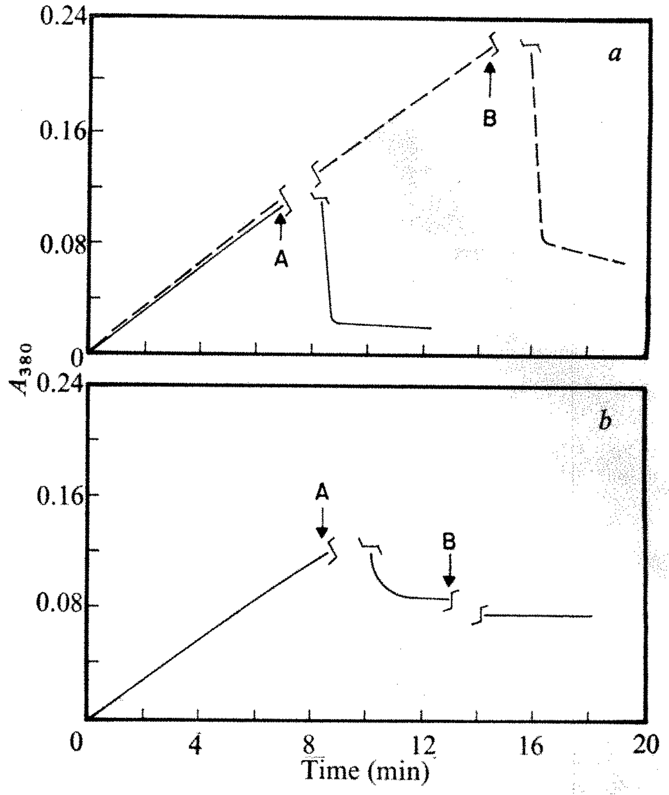

Fig. 2 Effect of glucose–glucose oxidase additions on the reduction of *in situ* generated transistory quinoid intermediates of chlorogenic acid. Quinoid intermediates were generated as described in Fig. 1 and their appearance monitored with time at 380 nm. *a*, Two separate experiments are shown : 3.3 mM glucose was included in the initial reaction mixture of the first experiment (—) and omitted from the second (- - -). About 7 min after addition of laccase each experiment was briefly interrupted (point A) with addition of 100 μl of commercial (Sigma) glucose oxidase (120 units). Immediately thereafter the 380 nm absorption was again monitored with time. The experiment lacking glucose failed to register a decrease in 380 nm absorption until glucose (1.0 μmol) was also introduced to the mixture approximately 8 min thereafter (point B). *b*, The same experiment as in (*a*) was repeated with 3.3 mM glucose in the initial reaction mixture, except 10 μl (45 μmol) of sodium azide was added to the sample cell 7 min after initiation of quinoid production by laccase (point A); approximately 6 min thereafter glucose oxidase (120 units) was added to the sample and the 380 nm absorption again monitored as shown.

Table 2 Effect of oxygen and glucose on the laccase–glucose: quinone oxidoreductase cycle

	Substrate	A_{575}	Comments
Experiment 1	DCIP	1.00	Incubated 30 min under nitrogen
		0.56	5 min after admission of air oxidised DCIP products seen in absorption spectrum
Experiment 2	DCIP+glucose	0.00	Incubated 30 min under nitrogen
		1.00	2 min after admission of air absorption spectrum identical with DCIP spectrum.

0.5 ml fungal enzyme extract (approximately 0.3 units laccase; 0.5 units glucose oxidase) and 0.33 μmol DCIP were mixed together in a final volume of 3.0 ml 50 mM potassium acetate, *p*H 5.0. Nitrogen was bubbled through the enzyme–substrate mixtures except as noted. The absorbance of DCIP at 575 nm was determined on a Model 11 Carey spectrophotometer; visible spectra of the reaction mixtures were also taken at selected intervals between 375 and 700 nm. Fungal enzyme extracts were prepared by extracting the semi-solid substratum of *P. versicolor* cultures in 50 mM potassium acetate buffer, *p*H 5.0, filtering the crude slurry through cheese cloth, and centrifugation to yield a cell-free 10,000*g* supernatant. Stock enzyme was recovered as an ammonium sulphate pellet (0–90% saturation).

The enzymatic oxidation of glucose by glucose oxidase is known to occur in two steps: (1) oxidation of glucose to gluconolactone through the transfer of two electrons to a flavin prosthetic group on the enzyme; and (2) reoxidation of the reduced flavoenzyme through a second two electron transfer to a suitable electron acceptor[4,14], and thus the capacity of oxidants to participate in the enzymatic oxidation of glucose rests in their ability to accept electrons from the reduced enzyme. It is noteworthy that the K_m of glucose for glucose oxidase decreases from 4.2 to 1.9 μM upon decreasing the oxygen tension in the gas phase from

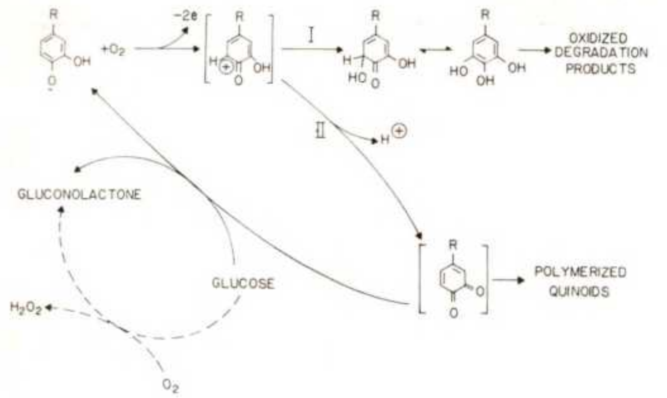

Fig. 3 Schematic flow diagram of postulated laccase–glucose: quinone oxidoreductase cycle and its significance in the degradation of lignol substrates.

20 to 5%, respectively, but that glucose oxidation is less than half V_{max} at atmospheric oxygen tensions in the presence of saturating concentrations of glucose[4,6,15]. Oxygen is thus a poor substrate of glucose oxidase, whereas glucose is an excellent substrate (for example, reductant) whether oxygen is present or absent from solution. Moreover, at physiologically low oxygen tensions the ability of quinone or free-radical lignol intermediates to compete with oxygen as oxidants of glucose oxidase would be expected to be of greater significance because of an improved ratio of quinoid concentration over that of oxygen. The experimental results of this study corroborate these observations.

Figure 3 outlines a metabolic role for glucose oxidase which may provide a rationale for laccase–glucose: quinone oxidoreductase cycling. Initial abstraction of electrons from a lignol substrate by laccase transforms the substrate into an electron deficient transition state intermediate, which may undergo nucleophilic attack by hydroxylation as illustrated by route I of Fig. 3. On the other hand, an electron shift and loss of proton may occur to yield a transitory quinone intermediate as shown by route II of Fig. 3. Without glucose: quinone oxidoreductase activity, transition state intermediates produced by laccase would accumulate, condensing and polymerising with products secreted into the microbial substratum. Glucose oxidase may thus serve two functions in the substratum: (1) to protect the metabolic processes of the microbial cell from toxic accumulations of quinoid intermediates; and (2) to greatly improve the efficiency of lignol oxidations by channeling substrates through productive degradative routes.

In view of these observations, the physiological significance of oxygen as a co-substrate of glucose oxidase is worth re-examining, possibly as a potential modifier of glucose: quinone oxidoreductase activity, because of its capacity to compete as an oxidant of glucose oxidase, and in the process to uncouple normal channeling of lignol oxidation products through the laccase–glucose: quinone oxidoreductase cycle.

Unusual mitosis in the red alga *Porphyridium purpureum*

Porphyridium purpureum (Bory) Drew *et* Ross (Syn.: *P. cruentum* Nägeli) is a classical laboratory organism and one of the few red algae easily grown in large quantities. This would make it an obvious candidate for investigation of red algal mitosis with the electron microscope. The nuclei are, however, quite small and fast dividing, so that previous attempts remained apparently unsuccessful[1,2] and left the much more complex species *Membranoptera platyphylla* the only red alga where mitosis had been satisfactorily described[3]. We are now able to report that mitosis in *Porphyridium* is not only quite distinct from that in *Membranoptera* but also presents an unique association of microbodies with the spindle poles.

In order to increase the chance of observing mitotic figures, a culture of *P. purpureum* strain 161 of the University of Indiana culture collection grown in artificial seawater[4] was synchronised by a 12 h light–12 h darkness cycle according to Gense *et al*[5]. modified by Knappe[6]. Cells collected the fourth day after the beginning of synchronisation, 8 h after the beginning of the light period (the best time for mitosis as estimated from cell count curves and observation of feulgen-stained material), were fixed with glutaraldehyde, postfixed with osmium, sectioned and stained with uranyl acetate and lead.

Despite the fact that several hundred cells were examined,

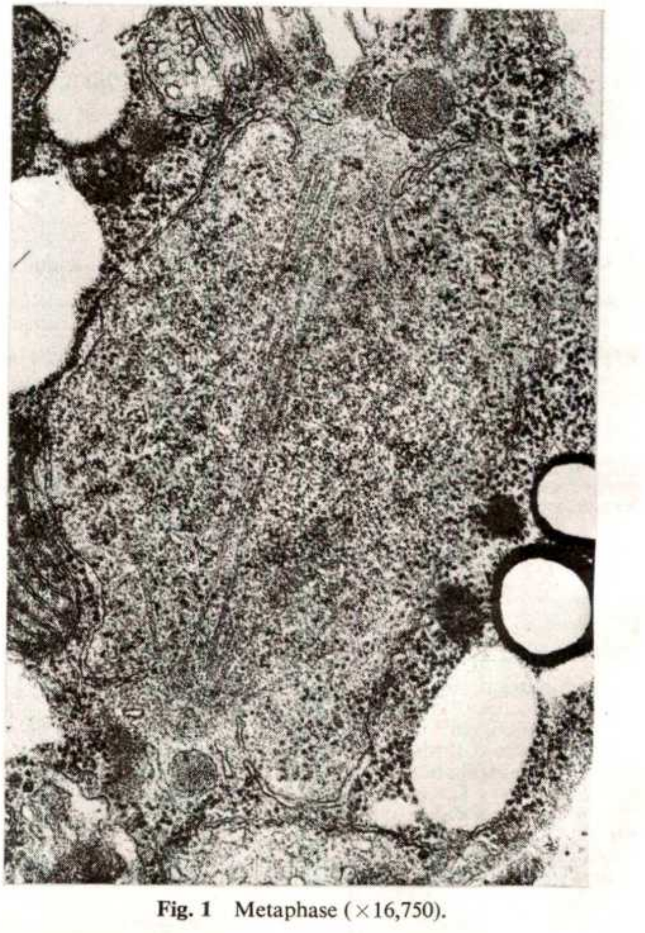

Fig. 1 Metaphase (×16,750).

only four were in metaphase and for only one did the plane of the section include both spindle poles (Fig. 1). The nuclear envelope is well preserved except for large polar fenestrae where microtubules end in a ribosome-free area delimited by fragments of endoplasmic reticulum and microbodies (one to three). No well defined pole body is apparent and the microtubules seem to be divided into a central bundle of interpolar ones and peripheral ones that end in small darker masses that might be badly condensed chromatin without kinetochores. The nucleolus is apparently dispersed, with some ribosome-like particles visible in the periphery of the nucleus.

A few tangential sections of nuclei that might be in prophase suggest that at that time an amorphous microtubule-organising centre might be present, to which extranuclear microtubules are connected (Fig. 2). This is however insufficient to demonstrate an extranuclear origin of the spindle.

Nuclear division and rebuilding of the nucleolus are performed before the onset of cytokinesis.

Microfilaments about 10 nm in diameter similar to those reported in other algal and fungal nuclei[7–9] have also been observed, but not in dividing nuclei (Fig. 3).

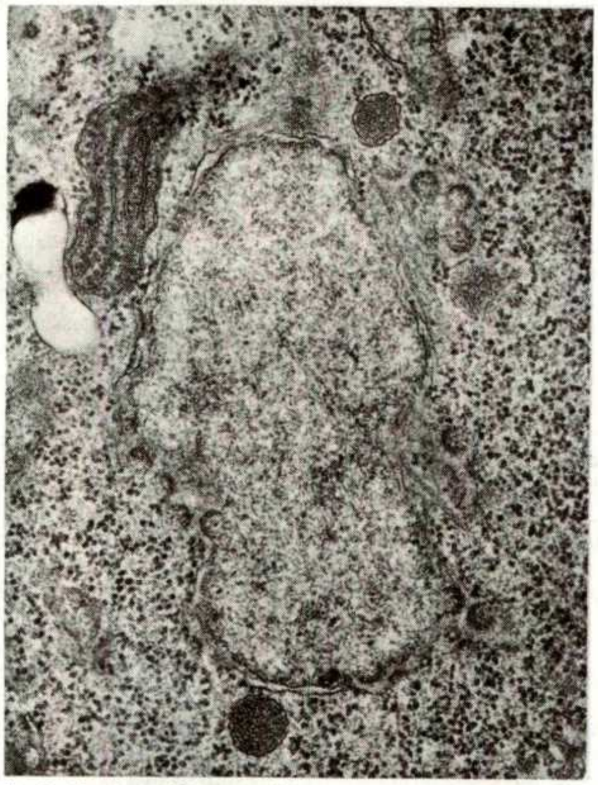

Fig. 2 Prophase (?); tangential section of the nucleus (×16,750).

It is notable that we have observed none of the figures previously interpreted as cytoplasmic invaginations in the nucleus during mitosis[1], although we have worked with the same strain. From further studies by those authors[2] it seems that those figures were attributable to a viral infection that did not manifest itself in our culture.

The reported nuclear behaviour of *Porphyridium* is quite distinct from that of the more complex red alga previously studied[3]. It lacks the polar rings and kinetochores (unless those structures have escaped our sections), the well condensed chromosomes and the doubling of the nuclear envelope by endoplasmic reticulum. The polar microbodies (a feature verified in three other nuclei) are as far as we know an unique feature. A microbody is pictured by Franke and Reau[10] near a dividing nucleus of *Phycomyces*, but other pictures seem to imply that this is not a regular feature. In *Pyramimonas*[11], a single large microbody has a peculiar behaviour during mitosis but might be more associated with the flagellar bases than to the nucleus.

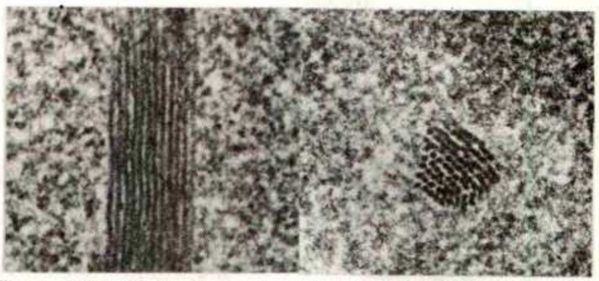

Fig. 3 Microfilaments in the nucleus: left, longitudinal section; right, transverse section (×33,500).

The microbodies are apparently similar to those previously studied in *Porphyridium* by Oakley and Dodge[12].

The large polar fenestra is rather similar to that of the Basidiomycetes *Poria latemarginata*[13] and the lack of condensed chromosomes is a typical feature of higher fungi but at the moment *Porphyridium* cannot be clearly related to any other organism on the basis of its mitosis[14–16].

Its mitosis is anyway not closer to that of Cryptophyceae[17] than that of *Membranoptera* and so does not change the situation in the controversy on possible relationships between Rhodophyceae and Cryptophyceae[18–19].

Studies of further red algae, especially the primitive ones would obviously be extremely interesting as the mitotic type of the group cannot be only characterised by what is known in *Membranoptera*.

Carotenoid transformations during chloroplast development in *Scenedesmus obliquus* PG1 demonstrated by deuterium labelling

THE unicellular green alga *Scenedesmus obliquus* (Chlorophyta), when grown photosynthetically, contains pigments (chlorophylls and carotenoids) similar to those of the chloroplasts of higher plants[1]. Several mutant strains[1] have abnormal pigmentation[1]. One of them, PG1, when grown in the dark accumulates the acyclic carotenoids phytoene (7,8,11,12,7′,8′,11′,12′-octahydro-ψ,ψ-carotene), phytofluene (7,8,11,12,7′,8′-hexahydro-ψ,ψ-carotene) and ζ-carotene (7,8,7′,8′-tetrahydro-ψ,ψ-carotene) in place of cyclic carotenes and xanthophylls, and cannot make more than trace amounts of chlorophylls. The pigmentation of light-grown PG1, however, is virtually identical to that of the wild type. When dark-grown PG1 is illuminated, the content of acyclic carotenoids decreases and that of cyclic carotenoids increases[2]. Time-course studies[3] agree with the hypothesis that the cyclic carotenoids produced on illumination are formed from the acyclic precursors that accumulate in dark-grown cultures. It has not been possible to confirm this by radioisotopic labelling, but we have now done so using deuterium labelling. Our procedure also provides a general method for following the kinetics of formation of important chloroplast constituents during chloroplast development in this and other organisms.

Wild-type *S. obliquus* can be cultured (autotrophically) in deuterated medium (99+% D_2O; ref. 4). By culturing *S. obliquus* PG1 in the dark on ordinary (H_2O) medium and then transferring to D_2O and illuminating we have developed a method in which deuterium labelling is used to examine changes that occur in the carotenoid composition of the organism during illumination. *S. obliquus* strain PG1 was grown heterotrophically in the dark, in which conditions it accumulated ζ-carotene, phytoene and phytofluene as its main carotenoids[1]. The cells were harvested, resuspended in D_2O without added nutrients, and starved overnight by shaking in the dark to deplete starch reserves. A mixture of air–CO_2 (95 : 5) was then bubbled through while the cell suspension was illuminated for 4 h. The main cyclic carotenoids, α-carotene (β,ε-carotene), β-carotene (β,β-carotene), lutein (β,ε-carotene-3,3′-diol) and zeaxanthin (β,β-carotene-3,3′-diol) were subsequently extracted and purified[1] and examined by mass spectrometry. The important features of the mass spectrum of β-carotene are illustrated in Fig. 1 and discussed below; similar results were obtained for the other carotenoids. Three features in the mass spectra are particularly important.

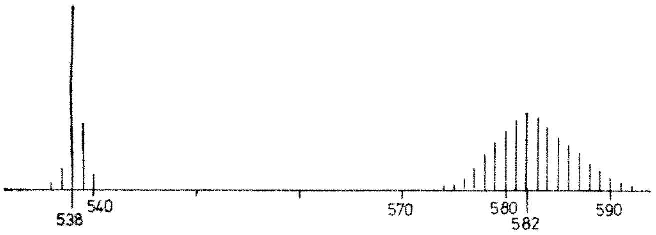

Fig. 1 Features of the high mass region of the mass spectrum of deuterio-β-carotene produced by *S. obliquus* PG1 grown in the dark and then resuspended in D_2O and illuminated.

(1) There was virtually no trace of the normal molecular ion of α-carotene or β-carotene (both $C_{40}H_{56}$) at *m/e* 536 or of lutein or zeaxanthin (both $C_{40}H_{56}O_2$) at *m/e* 568. There had therefore been virtually no synthesis of undeuterated cyclic carotenoids.

(2) In all cases by far the most intense ion in the high mass region corresponded to *m/e* (M+2) in the spectrum of the unlabelled carotenoid, that is at *m/e* 538 for the carotenes and 570 for the xanthophylls. This indicated that the most abundant molecular species in each case was one containing two deuterium atoms. The mass spectrum of recovered, uncyclised ζ-carotene showed only the normal molecular ion at *m/e* 540 ($C_{40}H_{60}$) with no ion at *m/e* 542 corresponding to a dideuterio species.

(3) The group of ions at approximately *m/e* 574–592 in the spectra of α- and β-carotenes and at approximately *m/e* 606–622 in the spectra of lutein and zeaxanthin, in each case accompanied by characteristic (M−deuterotoluene) fragmentations, indicated the presence of molecular species containing extensive deuterium labelling (average composition $C_{40}H_{10}D_{46}$ for carotenes and $C_{40}H_{12}D_{44}O_2$ for the xanthophylls). The relative intensities of these ion groups gave a measure (assuming similar volatilities for all the molecular species in the mass spectrometer ion source) of the extent of new synthesis of cyclic carotenoids from small molecules, for example CO_2 and D_2O occurring during illumination.

The cyclisation reaction of carotenoid biosynthesis (Fig. 2) is generally considered to be a proton-initiated process[5]. Thus if an acyclic precursor carotenoid is formed in ordinary (H_2O) medium and then cyclised in D_2O, one deuterium atom will be introduced at C–2 during each cyclisation, that is, bicyclic carotenoids will contain two deuterium atoms. The mass spectrometric assay therefore directly demonstrates that in greening *S. obliquus* PG1, α- and β-carotenes, lutein and zeaxanthin are all formed by cyclisation of existing acyclic precursors (for example ζ-carotene, presumably first desaturated to lycopene). Conclusions drawn previously[3] from the results of kinetic studies without isotopic labelling are therefore valid.

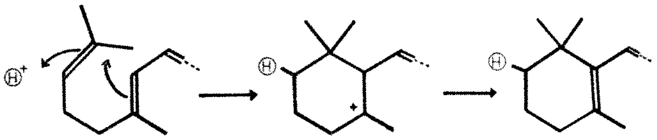

Fig. 2 Mechanism of the cyclisation reaction of carotenoid biosynthesis.

Perhaps the most important feature of this procedure is that, by mass spectrometric assay, molecules synthesised from preformed intermediates can be distinguished from molecules formed by new synthesis. Studies of the time-course of events occurring during chloroplast development are therefore possible. For example, when dark-grown PG1 is transferred to D_2O and illuminated, and aliquots of the greening cells are removed after various time intervals and the cyclic carotenoids are extracted and assayed by mass spectrometry, it is apparent that in the early stages of greening (up to 2 h) the cyclic carotenoids are derived mainly from the preformed cyclic intermediates, whereas after longer times the cyclic carotenoids are increasingly being produced by new synthesis. Note, however, that the greening process occurs much more slowly in D_2O than in H_2O.

This procedure clearly has potential as a general method for studying metabolic pathways or developmental processes that can be interrupted, for example by inhibition, mutation, lack of light energy, but can then be completed under appropriate conditions. If the first phase of the process (up to the interruption) takes place in ordinary (H_2O) medium and the second phase (after removal of the interruption) is allowed to proceed in D_2O or D_2O-based medium, then mass spectrometric assay of the type described above can be used to differentiate between compounds produced entirely during the first phase, entirely during the second phase, or, in appropriate cases such as cyclic carotenoids, formed during the second phase from intermediates produced during the first phase. The method can thus be used to obtain information about the origins of various chloroplast components, the time-course of their formation and their relative importance in the chloroplast structure, during development of algal chloroplasts. The method is also applicable to studies of the development of the photosynthetic apparatus in photosynthetic bacteria. We have used a related procedure to demonstrate the formation of cyclic carotenoids from accumulated lycopene in a *Flavobacterium* species and to determine the stereochemistry of the proton-initiated cyclisation reaction. (G. B., W. J. S. L., N. J. Patel and T. W. G., unpublished).

reviews

Curious little book on rabies

George M. Baer

Rabies: The Facts. Edited by Colin Kaplan. Pp. 116. (Oxford University: Oxford and London; Corgi: London, 1977.) Hardback (OUP) £1.95 paperback (Corgi) 75 pence.

THIS is a curious little book on rabies. If it is intended for a scientific audience, it is the first such book I know of without references. If it is a book for the general public, it contains highly specialised information on nucleoproteins, structural proteins of the virus, and comments rather advanced for the average reader such as: "In their model of rabies virus, Vernon and his colleagues have depicted the larger of the two M proteins (M_1) as being adjacent to the ribonucleoprotein".

The book is divided into seven chapters, begining with a discussion of the world problem, and emphasising the under-reporting of the disease. Under-reporting has also been discussed in a notable 1967 report by Sanmartín *et al.* (Sanmartín, Correa, Dueñas & Muñoz, Memorias del Primer Seminario Nacional Sobre Rabia, Medellín, Colombia, 155–161, 1967) in which 1.7% of 1,596 autopsies in the University Hospital in Cali, Colombia, showed that death was due to rabies.

It is unfortunate that no maps or tables are included in a discussion of world rabies epidemiology, and that the description of the flourescent antibody technique is not accompanied by a diagram making it a little more intelligible for the layman. The technique has been of tremendous value in rabies diagnosis and investigations.

The descriptions of the disease attests to the terror that rabid dogs once instilled in the hearts of English countrymen, much as it does today in thousands of people in most developing countries. It has often been noted that rabies infection in the field frequently results in antibody production in a sizeable percentage of animals, much as described in this book. This includes animals such as insectivorous bats (Burns & Farinacci *J. Infect. Dis.* **97**, 211; 1955), mongooses (Everard, Baer & James *J. Wildlife Dis.* **10**, 190; 1974), dogs (Doege & Northrop *Lancet*, **ii**, 826; 1974) and other fairly resistant species. Much is made of the two human recoveries from rabies (Hattwick *et al. Ann. Intern. Med.* **76**, 931; 1972; Porras *et al. Ann. Intern. Med.* **85**, 44; 1976), as well as one purported carrier dog (Veeraraghavan *et al., Ann. Rep. Pasteur Institute of Southern India*, 66, 1968), yet it has not been pointed out that these are bizarre exceptions to the rule.

The chapter on rabies virus itself by Crick and Brown is a complete description of the morphology, chemistry and structural subunits of the virus, and of rabies-related viruses. It also covers replication of the virus, synthesis of virus components and other products from infected cells.

The chapter on human rabies includes various aspects of the disease in man, including susceptibility, symptomatology, diagnosis and prevention. An amazing anecdotal series of cases of rabies transmitted from man to man is succeeded by a statement that "... there is no completely documented case of man transmitting rabies to man", in which case it seems pointless to even mention the dramatic anecdotal cases. Another amazing statement is: "For reasons which are unknown rabies is up to seven times commoner in men than in women: this also applies to animals". This statement may be applicable to man (see review by Hattwick in *The Natural History of Rabies*, Academic, New York, 1975), but it is certainly not for animals. Verts (*The Biology of the Striped Skunk*, University of Illinois Press, Urbana, Chicago and London, 1967) writes that "Of the 20 rabid striped skunks caught in northwestern Illinois, 19 (95.0 per cent) were females". This type of information should not be included unless it is properly documented.

The chapter on rabies in animals includes a table listing incubation periods for various species, with errors: for example, incubation periods of more than 5 months have been reported for foxes (Sikes, *Am. J. vet. Res.* **23**, 1041; 1962) and periods of more than one year have been reported in cattle (Abelseth & Lawson, cited by Bell, *The Natural History of Rabies*, Academic, New York, 1975). Photographs of humans and animals with rabies, as well as electron micrographs of rabies virus are included in this chapter. There is rightful emphasis on the variability of the signs in dogs, and on the fact that relatively few develop furious rabies. It is again unfortunate that no references are included; for example, I am not acquainted with the outbreak of rabies reported in pigs. Other curious statements such as "Deer are as prone to rabies as cattle . . ." should be documented. The chapter ends with the astounding suggestion that "There is a potential danger here (that is, Britain) that rabies might enter this country and become enzootic in mink much the same way it has become established in the mongoose. . . " One wonders why this has not already occured in the numerous countries where rabies is enzootic and mink are plentiful.

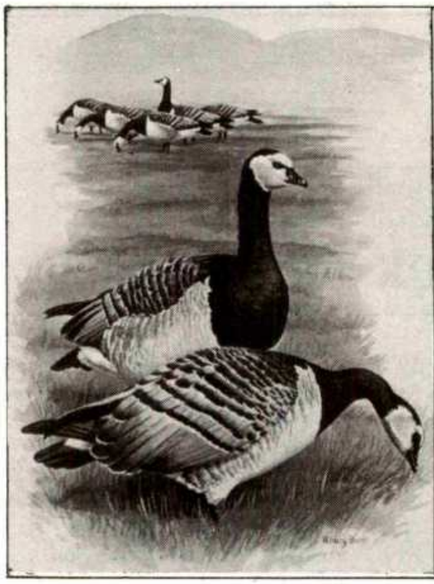
The next two chapters are on fox behavioural ecology and the prospects of wildlife rabies in Britain. They include a description of fox behaviour and rabies in the fox, with summaries of studies done in Britain and other countries. These chapters are basically well presented and include much useful information. The possible transmission of rabies from cats to foxes is emphasised, without any explanation as to why this mode of transmission is believed to occur. In fact, Wachendörfer has shown (*Dt. tierärztl. Wschr.* **69**, 555; 1962) that the case of rabies transmitted from foxes to cats are closely related and the two epizootiological curves can be virtually superimposed.

The short chapter on rabies vaccines by Turner encompasses most of what is known today about human and veterinary vaccines, with emphasis on the difference between pre-exposure vaccination (such as vaccination of animals and of people at risk to exposure in the laboratory), and post-exposure vaccination. □

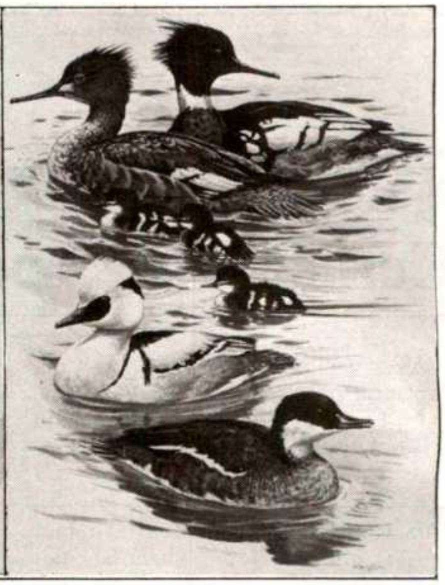
George M. Baer is Chief of the Viral Zoonoses Branch of the Center for Disease Control (Lawrenceville Facility), Lawrenceville, Georgia.

European wildfowl

Wildfowl of Europe. By Myrfyn Owen. Colour plates by Hilary Burn and foreword by Sir Peter Scott: Pp. 256. (Macmillan: London and Basingstoke, 1977.) £15.



Barnacle Goose



Red-Breasted Merganser (above) and Smew (below)

QUITE often popular books of this sort are written to support the illustrations and this may have been the original idea for this volume. The author admits that this book does not pretend to summarise all known information about wildfowl. He attempts to cover most aspects of the birds' lives unclouded by tedious detail and he confesses to a personal bias in what he has omitted. The first quarter of the book deals with taxonomy, waterfowl movement, populations dynamics, migration and man's relation to waterfowl. Helped as he has been by the scientific staff of the Wildfowl Trust, the author has included some new quantative information in these chapters. The final chapter of this section is spoiled by his unnecessarily chauvinistic attitude, which gives the reader the misleading impression that one can only see wildfowl in three localities in Britain—three reserves administered by his own organisation.

The remaining three-quarters of the book provides a brief history of all the species of wildfowl recorded in Europe. Many chapters contain new information resulting from research undertaken by the Wildfowl Trust: particularly valuable are the figures for European populations based on counts organised by the International Waterfowl Research Bureau, and the accounts of the feeding ecology of nearly all the main species of duck. But there is little about breeding behaviour in the individual accounts. Four useful appendices summarise information about nests, eggs and young of wildfowl, winter weights and measurements, winter food and waterfowl in captivity.

This volume is illustrated by coloured plates—for which incidentally there is no index or list—by Hilary Burn, a promising young bird painter whose work has developed rapidly. But because of her predeliction for the use of black to create shadows, many of the plates of the colourful species such as wigeon, pochard and mallard are sadly lacking in natural sparkle. The design of some of the plates could show more imagination and the scale is sometimes awry. Joe Blossom's line drawings are generally competent at underlining points made in the text.

Interesting though it is, I find it difficult to accept that this rather popular volume is really worth the £15 charged for it: while the wildfowl enthusiasts will buy it, the specialist would have expected something much more comprehensive. Costs might have been less if the margin had not been so wide—75 millimetres for a single page or 150 millimetres when the book is open.

Peter Conder

Peter Conder recently retired as Director of the Royal Society for the Protection of Birds.

Push-button biology

Human Biology: An Exhibition of Ourselves in the new Hall of Human Biology at the British Museum (Natural History), London. A permanent exhibition, admission free.

Human Biology: An Exhibition of Ourselves. Pp. 120. (British Museum (Natural History) and Cambridge University: London, 1977.) Hardback £5.00; paperback £1.95.

THE dinosaurs and whales, and halls of decorously deceased representatives of the animal kingdom, at the British Museum (Natural History) (BM (NH)) have been joined by an exhibition which requires more of the visitor than tireless legs and unglazable eyes. The Hall of Human Biology is the first fruit of the major reorganisation which is intended, during the next 30 years or so, completely to rearrange the museum's specimens. They have been presented for more than 100 years according to Victorian notions of the plan of the Creator, which are no longer deemed appropriate. In future visitors will be expected to discover as well as to learn, and the specimens will be accompanied by buttons to push, handles to turn and games to play. Although in Britain this represents a revolutionary new concept in museums, it has been flourishing abroad for some time in such centres as the Oregon Museum of Science and Industry in Portland.

In An Exhibition of Ourselves, which fills the Hall of Human Biology, visual, tactile and olfactory aids can be manipulated to reveal details of growth and development, and of the control of bodily functions and their responses to the external environment. Much of the material has been incorporated into the accompanying book, which consequently tells its story as much through pictures as through the text. In the tradition of such BM (NH) publications, the book can be used independently, although it follows closely the plan of the exhibition.

Willing learners, young or old, with some experience of biology textbooks should find that the exhibition usefully and enjoyably complements their knowledge. For them animated models will explain homeostatis and neuromuscular control; a slide show will clarify the events of gestation and birth, and an optical illusion will tell something about perception. Afterwards *Human Biology* will remind them of the concepts they have encountered.

Visitors with little or no aquaintance with biology, however, may have to concentrate quite hard on the exhibition. And that could be difficult when the maze of exhibits is swarming with exuberant youth apparently determined to flash all lights and ring all bells at once. But a subsequent session with the book will probably be very helpful for visitors who cannot absorb all the information offered by the exhibits.

The museum authorities foresee a need to control the flow of visitors through the exhibition, and they are waiting to see how it survives the rigours of the next few months.

Mary Lindley

Mary Lindley is Assistant Editor of Nature.

Life as a self-perpetuating information system

Genetic Evolution. By Chen Kang Chai. Pp. 341. (University of Chicago: Chicago and London, 1976.) £15.

THE theme of this work is that life is a self-perpetuating information system and that at all levels this undergoes revision or evolution. The author considers, in sequence, the evolution of prebiotic molecules, of genes, symbiosis, the evolution of chromosomes, of biological structure and function and of populations. In spite of protestations otherwise, this cannot be considered a text book; indeed its use as such would be irresponsible. Those without a broad elementary understanding of modern genetics would find this book difficult, and it contains much that should not be uncritically accepted by a genetics undergraduate. It is a hybrid between a collection of essays and a textbook (say, of population genetics); the phenotype of the organism is stimulating and interesting in places; biased and superficial at others. The subjects covered are so broad that response to a particular chapter is likely to be conditioned by previous experience of its subject matter.

Chapter 1 is concerned with the evolution of biological molecules and the genetic apparatus. It is straightforward and recalls the work of Oparin, Calvin and others on the evolution of organic molecules from inorganic precursors. The next chapter deals with the evolution of genes and perpetuates the belief that the rate of amino acid substitution (and thus the rate of change of DNA) is constant for particular proteins. This is no longer upheld by data for cytochrome C and haemoglobin. The α and β chains of haemoglobin have evolved at different rates, and the same chain has evolved at different rates during vertebrate history.

The third and fourth chapters deal with symbiosis as a precursor to sexual reproduction and with the evolution of eukaryote chromosomes respectively. These two chapters are absorbing but one is left with the uncomfortable feeling that the evidence for each thesis is tenuous to the extreme. When dealing with the evolution of structure and function the book is more convincing and the (freely admitted) sin here is one of omission. The remaining chapters largely deal with population genetics with the material arranged to suit the underlying theme of the book. Here, the discussion of genetic load seems uncritical as is the examination of the current controversy between the neo-Darwinists and those subscribing to neutral mutation theory. The author obviously believes that most variability is of selective importance; yet as with data on the constancy of the rate of amino acid substitution, he does not stress alternative arguments.

If one accepts this book's F_1 status (and protects the innocent), it is interesting and enjoyable. With appropriate supplementary material it should form the basis of many lively honours level seminars and discussions.

J. A. Bishop is Senior Lecturer in the Department of Genetics at the University of Liverpool.

Chemical lasers

Handbook of Chemical Lasers. Edited by R. W. F. Gross and J. F. Bott. (Wiley Interscience: New York and London, December, 1976.) Pp. x+744. £31; $49.

THE preface of this volume describes how a meeting was convened in California in September 1964 to discuss the possibility of nonequilibrium chemical excitation and pumping of lasers, and how by the close of the conference a young graduate student was able to claim that he had demonstrated the first photo dissociation laser. In that experiment excited iodine atoms were formed by the photoinducted rupture of alkyl iodine bonds; this work led naturally to the demonstration of chemically-pumped emission in photolytically-initiated hydrogen–chlorine explosions by the same workers (Kasper and Pimentel) in 1965. It is instructive to speculate why so few of the resultant publications in this interdisciplinary field have emanated from the United Kingdom or indeed why relatively few of the twenty authoritative contributors to this handbook work in western European laboratories.

The editors do not claim to have created a basic text book, but rather an up-to-date compendium of relevant (high gain) laser physics, the gas dynamics of reactive flows and the chemical kinetics of nonequilibrium reactions. Pulsed and continuous hydrogen–halide lasers, the carbon monoxide laser, high power photochemical iodine lasers and metal-atom oxidation lasers are treated in detail; between 40 and 240 references per chapter ensure that most of the published journal and report literature between 1967 and late 1974 is well represented. Problems of numerical (gain) modelling certainly merited (and received) a chapter of their own; rather unexpectedly the treatment of optical resonators also extended to some 120 pages. Like many of the other contributions, however, this chapter (by Chester and Chodzko) was a delight to read; their treatment of stable and unstable resonator theory, and the complications introduced by the laser-gain medium in matching theory to experiment, is a jewel of conciseness. The book is well produced and edited, a 'must' for libraries, but rather expensive for the individual research worker.

Explanations in criminology

Behaviour and Misbehaviour: Explanations and Non-Explanations. By Nigel Walker. Pp. ix+154 (Blackwell: Oxford, 1977.) £5.

MOST new disciplines go through a period of introspection in which they examine the philosophical status of their theories and the adequacy of their methods. Criminology has not yet emerged from this stage, and in *Behaviour and Misbehaviour* Professor Walker examines the nature of explanation in that subject.

He distinguishes between "necessity explanations" and "possibility explanations". The former are used to explain regular events such as the daily rising of the Sun or the expansion of a gas on heating, the latter to explain exceptional or unique events. If an iceberg appears as far south as Rockall, we do not ask why it was *necessarily* there but what made it *possible* for it to be there: the answer required is a narrative involving such factors as a particularly hard winter in Greenland, the prevailing ocean currents, and the existence of strong north-westerly winds. Professor Walker calls the former type of explanation "scientific" and the latter "narrative". He then argues that because much criminal behaviour is exceptional, criminologists may have to be satisfied with narrative rather than scientific explanations. He is probably right: even rates of crime, as well as individual crimes, are determined by many interacting features some of which may be unique to a given society. But it is not clear that the difference between theories in the physical and social sciences is entirely captured by the distinction between "narrative" and "scientific" explanations: as Professor Walker acknowledges, even the physical scientist usually has to fall back on the narrative explanation to account for individual events such as the failure of a bridge.

A further distinction drawn by Professor Walker is that between explanation by analogy and explanation in terms of mechanisms. The difference is by no means clear-cut: an explanation by analogy may in fact be implicitly proposing a mechanism the details of which are not fully worked out. When Harvey had the insight that the heart was a pump was he suggesting an analogy or a mechanism? Exception can be taken to Walker's contention that explaining human behaviour by computer simulation is only giving an analogy: a computer program can represent the mechanisms underlying behaviour in just the same way as a set of equations can represent the mechanisms underlying the behaviour of a physical system.

Some of Professor Walker's omissions are suprising: in discussing scientific explanations he says little about formal rigour, simplicity, elegance or generality. He does, however, rightly castigate his fellow criminologists for the idiocy of some of their disputations such as the controversy over whether a given phenomenon can only have a single explanation and the dispute about the range of phenomena that fall within the province of criminology. He also gives short shrift to the arguments of Peters, Winch and others that human behaviour can never be understood in terms of causes.

I have two complaints about the book. For its exorbitant price, one might reasonably have expected the publishers to have hired a more conscientious proof reader. The second complaint is more unusual: although the book raises interesting issues, it is too short to do justice to the complexity of its subject matter, and it should have been several times as long.

Stuart Sutherland

Stuart Sutherland is Director of the Centre for Research on Perception and Cognition at the University of Sussex, UK.

Enzyme kinetics

Enzyme Kinetics. By D. V. Roberts. Pp. 326. (Cambridge University: Cambridge, London, New York and Melbourne, 1977.) Hardback £15; paperback £5.50.

THIS book deals with the use of mathematical expressions to describe the behaviour of enzymes and enzyme systems. Although the author works through the derivations of many of the equations that he presents, some familiarity with the use of determinants and the calculus is necessary if the reader is to follow the arguments used, and the book could not be recommend to mathematically weak students. For those who are not frightened-off by the mathematical treatments used, the author's comparison between the use of determinants and the schematic King–Altman procedure for deriving initial-rate equations is valuable, as is his treatment of the use of the Laplace–Carson operator method for solving the differential equations describing pre-steady-state behaviour. At times the derivation of equations seems to take precedence over consideration of the phenomena that they attempt to describe. In the chapter on allosteric proteins, for example, it is unfortunate that the author does not give more emphasis to the predictions made by the different models that he considers and to ways in which they may be distinguished.

The coverage given to different aspects of enzyme kinetics varies greatly and some topics, such as the effects of *p*H and temperature on enzyme activity, are given rather shallow treatments. In some places the analyses presented are misleading. The section on the use of product inhibition as an aid to defining kinetic mechanism, for example, fails to consider the effects of abortive ternary complex formation in random mechanisms and thus predicts an inhibition pattern for the rapid-equilibrium case which is in fact rare. In addition failure to distinguish clearly between the exclusive and non-exclusive cases of the concerted model of co-operativity leads to confusion in the analysis of the curve shapes predicted by this system. The author's differentiation between the steady-state and rapid equilibrium treatments of kinetic mechanisms is also confused and this is particularly evident in his treatment of non-competitive inhibition.

The main strengths of this book lie in its treatments of the kinetics of coupled enzyme systems and of computer simulation methods. This latter chapter, which considers the use of both analogue and digital computers, is particularly valuable since this important topic is usually ignored in books of this type. The author's enthusiastic treatment should capture the interest of many students and although the section on digital methods would not be sufficient to enable the reader to write his own simulation program, it provides an excellent introduction to the terminology and methods used. The sections on the use of analogue computers define the components used and give sample programs for simple kinetic systems. These programs should be sufficient to stimulate many enzymologists with access to an analogue computer to take this approach further.

K. F. Tipton

K. F. Tipton is Lecturer in Biochemistry at the University of Cambridge, UK.

newly on the market

These descriptions are prepared by the staff of *Nature* on the basis of material provided by manufacturers. The Reader Enquiry Coupon faces the inside back cover.

Miniature implantable pump. Alzet. The Alzet Osmotic Minipump allows study of the effects of continuous delivery of solutions in small laboratory animals. The Minipump is an implantable, self-contained, self-powered infusion system small enough to be placed subcutaneously or intraperitoneally in mice or rats, which once implanted, delivers solutions for up to 7 d without the need for external connections or frequent animal handling. The Minipump consists of a drug reservoir made of a flexible, impermeable material surrounded by a sealed layer containing an osmotic agent, all of which is contained within a semipermeable membrane. The Minipump surface is biocompatible and the pump gives a controlled, continuous delivery of solution, viscosities up to 100,000 cP.

Pipet stand. Variable Volumetrics. The D-2 pipet stand is made of transparent black plastic. It has stations for holding 3 Finnpipettes in the 1–1,000 μl range and 1 Finnipipette in the range 1,000–5,000 μl. It has good storage capacity for tips. Dimensions: 11 inch by 7½ inch by 6 inch.

Circle No. 42 on Reader Enquiry Coupon

Microstirrer. T.E.M. The Temtron will continuously stir micro quantities of aqueous chemical compounds. Previously this has not been possible under certain restrictive operating conditions. A method is now available allowing effective stirring, also addition of further preparations to existing compounds without ever handling the cuvette or disturbing the sensitive, fully enclosed detector system of the analyser. Stirring rate is continuously variable from 0–30 Hz. An 11 mm × 11 mm × 5 mm energiser capsule is placed under the cuvette and drives a Teflon-coated stir bar magnet. Cuvettes (e.g. 1 ml) having internal physical shape restrictions as small as 3 mm × 10 mm opening, normally impossible to stir, can be accommodated. The microstirrer does not interfere with the light sensing detectors.

Circle No. 43 on Reader Enquiry Coupon

Automatic photometer. Anaspec. The Biophotometer is useful in microbiology, bacterial research, the control of sulphamides and antibiotics, cancer research, oceanography and biology. Monochromatic light is presented successively to six separate cultures, each contained in an agitated temperature controlled environment. The measured optical transmisison is then monitored on a six point recorder for the growth period of the culture.

Circle No. 46 on Reader Enquiry Coupon

Shock chambers. Tenney Engineering Inc. Controlled by the Tenny DigiTenn microprocessor programmer, the multi-compartment cabinets perform all operations automatically once the desired sequence has been keyed into DigiTenn. Thermal shock chambers have two compartments, one at −65 °C, the other at 204 °C. Test specimen is transferred between thermal spaces, alternately shocking the item with extremes of heat and cold. In a typical DigiTenn controlled model, seven event channels determine temperatures in each chamber, time of work transfer from each chamber individually. time interval for temperature recovery, and number of transfers completed before automatic shutdown.

Nanotech vacuum coater

Vacuum coaters. Nanotech. The Semprep 2 sputter coater unit has automatic and manual operations. Facilities include specimen etching, water cooling of both specimen and and target, triode systems to minimise electron heating effects and controlled argon flushing and venting. Variable sputtering voltage up to 3 kV at current levels up to 150 mA; integral two stage 3 $\mathrm{m^3\,h^{-1}}$ rotary vacuum pump with pirani gauging, complete metal pipework and viton seals to reduce contamination levels.

Circle No. 46 on Reader Enquiry Coupon

Preparative ultracentrifuges. MSE. The Prepspin 65 and Prepspin 75 feature a new type of speed selector, a water shut-off valve to conserve water, a new semi-hermetic refrigeration unit, a brush warning indicator to indicate when brushes need attention or renewing, automatic shut down of gas ballast, a new design of oil mist filter, cushion start, and a completely redesigned control panel.

Circle No. 47 on Reader Enquiry Coupon

Tweezers. Welwyn Tool. Suitable for accurate handling of small, delicate components in the engineering, electronics, optical, chemical and other specialist industries, Granit tweezers have a smooth satin finish and are available with a variety of point configurations, including long and short fine, super fine, extra long, oblique, angled and curved. Length from 4 to 5 inch. Stainless steel and non-magnetic versions are available, the latter particularly suitable for handling small ferrous components. The non-magnetic models are resistant to most corrosive chemicals.

Circle No. 48 on Reader Enquiry Coupon

High speed servo recorder. J. J. Lloyd. The CR600 is a new two pen flat bed recorder combining fast writing speed with high accuracy. The recorder, in corrosion-resistant, brushed stainless steel case is suitable for vertical or horizontal use and is provided with chart take up facilities for both 'Z fold' and roll chart paper. Electronic limit switches deccelerate the pens at the end of their travel reducing wear often associated with high speed servo recorders. The advance specification includes an 18-speed reversible electronic chart drive ranging from 0.01 mm $\mathrm{min^{-1}}$ to 10 mm $\mathrm{s^{-1}}$, a sensitivity range from 5 μV $\mathrm{mm^{-1}}$ to 0.5 mV $\mathrm{mm^{-1}}$ by stepped attenuator with a vernier span control to provide complete range overlap. Special facilities include an internal voltage reference for spot calibration checks at any sensitivity setting, a 1,000% precision calibrated suppressed zero, remote controlled chart drive, pen lift and event marker. The chart width is 250 mm and writing speed exceeds 600 mm $\mathrm{s^{-1}}$. Options include retransmitting potentiometers on both channels and an integrator.

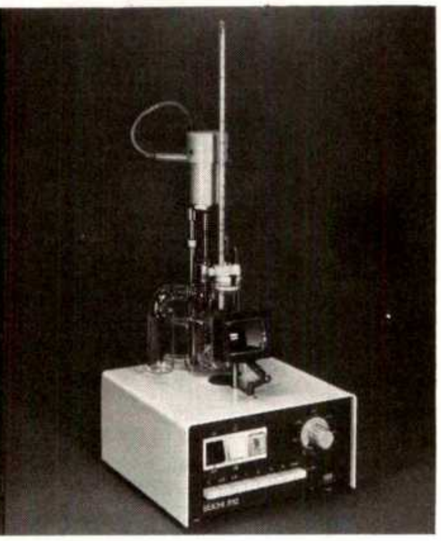
Buchi nitrogen distillation unit



Buchi melting point apparatus

Distillation unit for nitrogen determination. Büchi. The 320 is built into a housing with the glass parts protected from breakage, has built in storage tanks (5 l) for sodium hydroxide solution and for distilled water, the residue can be sucked out of the vial after distillation and the digestion tube also serves as distillation vial; it is, therefore, unnecessary to transfer the sample.

Circle No. 50 on Reader Enquiry Coupon

Melting point determination apparatus. Büchi. The 510 has an immersion depth of samples and thermometer of 40 mm regardless of the oil temperature. By this means, the 510 corresponds with the method of European Pharmacopoeia (capillary method). The new model also permits the use of Pharmacopoe-Thermometers calibrated at an immersion depth of 40 mm, with a subdivision of 1/5 °C.

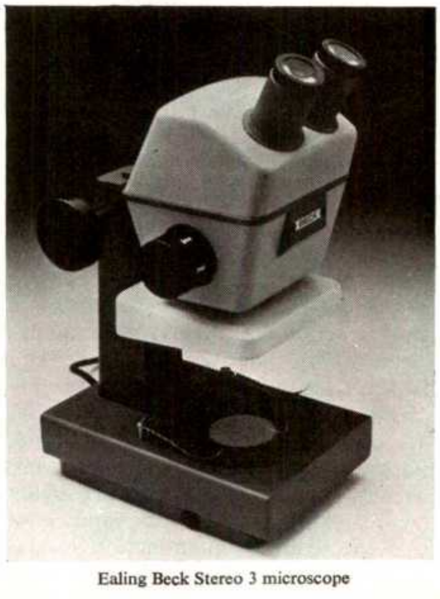
Circle No. 51 on Reader Enquiry Coupon

Stereo 3 microscope. Ealing Beck. Binocular optical design with a 10° convergence angle provides a stereoscopic effect suitable for inspecting such objects as laminated substrates in integrated circuits. Three optical systems of different magnification are included in the microscope head. The objective lenses for each magnification are mounted in a rotating turret which can be operated from either side of the microscope head. A parfocal system ensures that the object being viewed remains in focus at all magnifications. A useful feature is the long working clearance between the object being viewed and the microscope head. Depending upon magnification, the working clearance on the Stereo 3 can vary between 100 mm and 150 mm and is ideal for manipulative operations such as the bonding of miniaturised circuits.

Circle No. 52 on Reader Enquiry Coupon

Cell harvester with pre-programmable four wash sequence. Dynatech. For techniques where it is desirable to harvest cell cultures with more than one wash fluid, the Multiwash has been designed to deliver, in sequence, up to 4 wash fluids, including TCA, completely automatically to a row of 12 wells of a Microtiter plate, while simultaneously aspirating the contents of each well onto a fibre glass filter for subsequent analysis. Simple push button control enables selection of any combination of wash fluid; and wash times for each fluid may be independently varied between 2 and 60 s by pre-programmable time controls. Water vacuum may be sufficient for operation but a suitable vacuum pump is an option, if mains pressure is insufficient. Also standard inter-changeable wash/aspirate heads to facilitate harvesting from standard test tube racks and also have the facitity to manufacture special heads to customer specification, if desired.

Circle No. 53 on Reader Enquiry Coupon



Ealing Beck Stereo 3 microscope

Tubular filtration system. Millipore. The Steriflo system is designed to handle product volumes up to several hundred litres, and is ideal for applications such as: final filtration on filling machines, batch filtration and particle removal filtration. The system has a unique tubular membrane filter which combines the simplicity of disk filters with the ruggedness of conventional cartridges. Composed of cellulose ester membranes, this new filter is a hollow capless tube sheated internally by a layer of high wet-strength cellulose and externally by a monolithic polyethylene web. Each end of the tube is permanently edge-sealed with a dip coating of urethane. Product flow through the filter is from inside (upstream), out (downstream), providing high resistance to operating stresses. Where extended filter life is required, tubular Steriflo prefilter is also available that can be concentrically installed in the same housing. Also composed of cellulose esters, this tubular prefilter is free of asbestos and glass fibres, making them suitable for parental processing.

Circle No. 54 on Reader Enquiry Coupon

Radiation alarm monitor. Philips. The PW 4544/07 alarm monitor is designed to ensure a safe environment in X-ray analytical laboratories. It provides continuous confirmation that radiation levels are clearly within pre-set safety limits and that rooms containing X-ray producing equipment may be entered safely. The PW 4544/07 is designed for detection of 'soft' X-rays. The monitor is supplied with an external probe containing the end-window tube ZP 1600 (18507) which is fitted with a $1\ \text{cm}^2$ window to cover the range 0.02–$200\ \text{mR h}^{-1}$ (50 keV). The required alarm level indicated by red light and buzzer may be preset set at any point in the range.

Circle No. 55 on Reader Enquiry Coupon

Ultra-low-temperature cryogenerator. Philips. A compact cryogenerator, supplying cold in the 20 K and 80 K ranges simultaneously. The standard type K-20 cryogenerator, is particularly suitable for cryopumping, in high-vacuum or ultra-high-vacuum systems. The cryogenic pump is probably the preferred device for applications like space simulators, linear accelerators and thin-film deposition. The unit can be incorporated into systems designed for these purposes, including industrial coaters. Other application fields include gas liquefaction systems and low-temperature refrigeration systems.

The educational version of the K-20 provides additional measuring devices which allow students to carry out complete evaluations and assessments of various cryogenic phenomena.

Million-dollar problem—billion-dollar solution?

THE OECD report on the transport of air pollutants which Dr Barnes summarises on pages 92–93 is bound to resurrect some political problems that have been held just below the surface whilst the report was being prepared. The most important is likely to be the question of whether the United Kingdom should assume any responsibility for the effects of acid rainfall in Norway.

In the past thirty years the greatly increased use of tall smoke stacks by industry has been a blessing to those who live in industrial areas and who are no longer bathed in the acidic fumes of sulphur dioxide and sulphates. But the disagreeable material is now not simply dispersed over a wider area surrounding the smoke stack; much of it resides for a long time in the mixing layer that extends to a height of about 1,200 metres and which has been described as a travelling garbage can. The material is eventually either dry-deposited or brought down to the earth as acidic precipitation.

The OECD study reports sulphur deposition levels in rural areas in 1974 and attempts, by an understanding of prevailing winds and precipitation, to estimate how much of the material comes from the country in question, and how much from elsewhere. A table attempts to summarise the export–import budget for most European countries (including estimates for Eastern Europe). It is open to misinterpretation by politicians who do not appreciate the very large error bars (at least ± 50%) that must be applied to the data and the relatively short period of reporting (one year).

Even so, some interesting figures emerge. In many countries exports and imports of sulphur roughly balance, but Austria, Finland, Norway and Sweden and Switzerland each involuntarily import more than twice what they export. Denmark and the United Kingdom, on the other hand, export much more sulphur than they import.

The United Kingdom is the largest sulphur-emitter in Europe, putting 1.8 million tonnes into the atmosphere in 1974 (remember, however, that the figures must not be read too precisely). Less than half of this comes back to earth in the UK—most of the rest of Europe getting a dose of British sulphur. In the case of, say, West Germany, the dose is relatively small compared with what West Germany administers to herself. But Norway, where the clouds that pass over Britain often deposit their rain, receives roughly a quarter of her total sulphur deposit from British sources, double the contribution she makes from her own smokestacks.

This in itself by no means makes Norway into an exceptionally polluted part of the world—wet deposition of sulphates in southern Norway runs at about the same level as in much of the rest of Europe. But a lot of this sulphate resides in snow for several months and is the first to melt when temperatures rise in spring. The acid flush down rivers (pH 3 to 4) then kills fish, doing damage to the value of around $1 million. Sulphur also does other damage, of course, through corrosion and possibly by affecting agricultural productivity (though this is not yet well understood) but such damage is probably common to many countries whereas the fish kill problem is mainly relevant to Norway. It has also to be said that Norway worries about its declining environment in much the way the United Kingdom worries about its declining economy.

But now we know a little better what happens to sulphur, what is going to happen? Norway, which in the past has arranged for journalists to be flown to see the ravages caused by British pollution, will presumably go on the offensive again and demand better removal of SO_2 and sulphates at source. The United Kingdom will say that the study represents only one year and is of necessity so inexact that policy decisions cannot be based on the report.

The bleak fact is that this diseconomy, on a scale of ten million dollars at most, can only be countered by corrective action on a Europe-wide basis costing at least one thousand million dollars, maybe ten times as much. There is, of course, a solution of sorts, and that is for Britain to supply Norway with limestone to be added to lakes during the acid flush. No-one is yet sure that this will save the fish without some other side effect emerging. And of course it is of the nature of a technological fix—a now much reviled practice; but so, for that matter, would be anything attached at vast cost to chimneys. Nonetheless, the Norwegian government would be foolish to reject such a proposal out of hand—as seems quite likely. An insistence on removing pollution at source calls for so much investment and will generate so much international ill-will that any more flexible solution must first be considered. □

Twelve months after Séveso

A YEAR AGO last Sunday, Séveso 'happened'. A trichlorophenol reactor at the Icmesa chemical plant there spewed its contents over the surrounding area. They included about 1 kg of a highly toxic by-product, 2,3,7,8-tetrachlorodibenzo-paradioxin, known as dioxin. Controversy has raged ever since. It has involved both the plant's Swiss owners (Givaudan, a subsidiary of Hoffman-La Roche) and the Italian authorities; the scientific, legal and other aspects of the disaster; and, above all, the many people affected directly or indirectly by the dioxin. Séveso has received probably the most extensive media coverage ever accorded to the site of an industrial accident, and is a watchword for pollution.

Amidst all this two facts about the disaster are irrefutable, their consequences disastrous. The first was the venting of the reactor discharge directly to the atmosphere, an obvious fault of design. The second was the two-week delay in evacuating residents from the area, responsibility for which cannot with certainty be established but is part of the deliberations of the Italian court investigating the accident. For the people exposed to the dioxin, the health picture shows 106 children with the skin disease chloracne, but no evidence of immunological damage; no evidence of malformation attributable to the dioxin in the foetuses legally aborted from Séveso women exposed to the chemical, and no evidence of chromosomal damage in these foetuses; and a number of children born with abnormalities in the Séveso region which is reported to be no greater than the statistical norm for the area.

The plan to monitor the health of everyone exposed to the dioxin, though medically and politically necessary, will not be a true epidemiological survey of 'dioxin risk'. A more selective survey of categories of 'high, low and non-risk' groups is under review and will yield results more rapidly. There are fewer grounds for optimism over the question of decontamination policy for the removal of the dioxin. The section of Séveso which housed most of the evacuated residents has been decontaminated by the plant's owners and pronounced safe for habitation. But the methods to be adopted for the remainder of the contamination area are still disputed.

What are the wider implications of Séveso? The issue of reform of the abortion laws in Italy is one. Another concerns one of the proposals of the 1976 World Health Assembly which advocated that WHO collate information on birth defects in the populations of member countries; the collation is now more urgent than ever. The lessons for the general public, the chemical industry and governments are obvious. There are dangers involved in the operation of chemical plants. And the cost of disasters in the industry is great. Governments need to keep their pollution control measures under constant review. The fact remains, however, that it takes a major disaster to make things happen; and that has been of little comfort to the people of Séveso over the past 12 months. □

Rational containment on recombinant DNA

The US National Institutes of Health has recommended that all recombinant DNA experiments, involving any animal virus, should be subject to the highest containment conditions, even though other work with the intact virus may require less stringent conditions. Lennart Philipson, of the Department of Microbiology, Uppsala University, Sweden, and Pierre Tiollais, of the Institut Pasteur, Paris, put forward the case for categorising recombinant DNA experiments involving animal viruses more rationally.

THE development of molecular genetics has depended largely on the detailed analysis of bacterial viruses, the bacteriophages, and their use to transfer bacterial genes between bacteria which do not normally recombine. Animal viruses now promise to provide a similarly detailed insight into the molecular mechanisms of gene expression in animal cells, which will undoubtedly contribute to an understanding of man and his domestic animals both in health and disease and, it is hoped, contribute to the development of medical and veterinary science.

Restriction enzyme mapping of the viral genome enables regions of interest to be excised and analysed. In many cases the full development of this work requires the use of recombinant DNA techniques to purify and clone the resulting portions of the viral genome. Animal viruses can also be used as vectors for introducing other eukaryote DNA into animal cells in which its expression may be studied. At present, however, the guidelines on recombinant DNA research laid down by the US National Institutes of Health (NIH) require almost all recombinant DNA experiments involving animal viruses to be carried out under the highest containment conditions. In practice these requirements preclude most experiments.

Animal viruses as a class are unfortunately regarded by the general public and the uninformed scientific community as rather mysterious entities which cause pandemics, epidemics and isolated cases of dreadful infectious diseases against which there is no remedy. Scientists themselves have coloured this picture by suggesting that viruses may cause cancer in man, implying to the layman that cancer is an infectious disease. In reality, animal viruses are extremely diverse; some are known to be highly infectious and pathogenic. Others seem to be harmless. It should therefore be mandatory to discriminate between different viruses according to their pathogenicity to man and other mammals when formulating guidelines for the use of viral genomes in *in vitro* recombinant DNA research.

The conjectural hazards envisaged arise from the (hypothetical) risk that virus genomes, when introduced into bacteria or when used as vectors for introducing DNA into mammalian cells, may give rise to "new infectious entities" or may transfer their pathogenic or tumour-producing capacity from the new host back to man or other mammals. Both types of risk depend on chains of events with low probabilities.

Against these arguments it should be considered, first, that the transfer of all or part of the viral genome to bacterial cells may not be an entirely new event. For millions of years prokaryotic organisms have been exposed to eukaryotic DNA and several microorganisms have efficient systems of transferring DNA over recombinant barriers. Second, the development of a 'new infectious entity' would probably require expression of the viral genes in the prokaryotic cell. This must have a low probability since most genes from eukaryotes and viruses, which have been transferred up till now, are not faithfully expressed as RNA or protein in bacteria[1-4]. Even if the inserted viral genes are expressed the resulting risk would not be greater than that from production of viral proteins in cell cultures, since only fragments of the viral genomes will be inserted in the experiments proposed.

The conjectural hazards may therefore be confined to the transfer of viral nucleic acids from the modified bacterium to an animal or human host. This would require a chain of events, each of low probability: the bacterium containing hybrid DNA must first escape from the laboratory and then establish itself in a new host. The viral nucleic acid must then enter the cells of the new host, and there express its tumorigenic or other harmful properties. Even without considering containment we are probably discussing probabilities in the range 10^{-20}–10^{-28} for the transfer of harmful genes into the new host.

Against this background it is obviously necessary to prohibit experiments with viruses such as Lassa fever virus or Marburg virus, which are considered to be high risk viruses in diagnostic laboratories; but it is not clear that viruses classified as low risk, such as adeno, SV40 and polyoma viruses, need such high containment. SV40 virus has already been injected accidentally together with polio vaccine into millions of human subjects without any registered harmful effects[5,6], although antibodies against SV40 appear in the serum. Some adenoviruses infect humans readily and about 50–80% of the population develop antibodies to adenovirus types 1 and 2 from the age of 5–10 years[7]. Even the adeno–SV40 hybrid viruses which were originally isolated when adenovirus vaccines were developed in monkey kidney cells have been introduced into large groups of military recruits as an inactivated or live vaccine without any detrimental effects[8,9]. Careful studies have failed to find an association between adenovirus transcripts, T antigens or other adenovirus products with tumours in humans[10,11].

Normal biochemical work with adeno and SV40 viruses is considered to fall into the low risk category under guidelines published by the National Cancer Institute and those from the Center for Disease Control, Atlanta, Georgia. These regulations allow the use of large amounts of virus. Milligram quantities of viral DNA are handled regularly by investigators and technical personnel in several biochemical laboratories. Provided that expression of virus DNA is prohibited in the bacterial cell, which is likely (see above), it must be more risky for personnel to handle viral DNA than to insert it in a bacterial vector. The NIH guidelines request P4 and EK2 conditions to handle partial or intact viral DNA in a prokaryotic host although as we have pointed out the risks envisaged are comparable to or lower than those encountered when working with intact virions. It is possible to claim that virions present a higher risk since as long as the protein coat is present the virion may possibly escape from the laboratory and infect humans. Thus, there seems to be a disproportionately high containment requirement for work with animal virus genomes in bacteria.

It is also difficult to understand the containment requirements for work with eukaryotic vectors. In the case of SV40 it has been established that SV40 DNA will form hybrids with cell DNA when cells are infected at high multiplicity[12,13]. Such experiments are in essence shotgun experiments, but since no *in vitro* recombination is involved it is considered a low risk experiment requiring no containment facilities. If a similar experiment is carried out *in vitro* between DNA from the same cell and SV40 virus DNA (probably with lower efficiency), it is labelled as P4 according to the NIH guidelines. Insertion of SV40 sequences into adenovirus DNA also occurs frequently when the two are cultivated together, as exemplified by the adeno–SV40 hybrid viruses[14,15] and new hybrids recently developed (J. Sambrook and G. Fey, personal communication). To take advantage of the natural recombination between SV40 and adenoviruses requires only a moderate risk containment facility, but the NIH guidelines absolutely forbid these experiments using recombinant DNA techniques. Here there is also a distinct discrepancy between the guidelines and other regulations for the study of animal viruses.

Most of the confusion is probably due to the fact that natural and artificial recombinant DNA reserch has not been considered as a whole. Only the new *in vitro* recombinant DNA technique has formed the basis for developing the NIH guidelines, although guidelines for work with dangerous microorganisms have been in existence for a long time. Consistent rules for all recombinant DNA research are therefore needed.

A good definition of recombinant DNA research might be that suggested by the Standing Advisory Committee on Recombinant DNA of the European Molecular Biology Organisation (EMBO): recombination of DNA molecules of different biological origin by any methods that overcome generally recognised natural barriers to mating, infection and recombination, to yield molecules that can be propagated in some host cells and the subsequent studies of such recombinant DNA molecules. *In vitro* recombinant DNA research is only a subsection of this definition. Within the broader meaning of the term there are several experiments now carried out in low risk containment according to generally accepted guidelines, which must be analysed and compared with the *in vitro* techniques before any regulatory guidelines are issued. It is, for example, possible to transfer the genome of several animal viruses into the capsid of unrelated viruses[16–19], and thereby increase the host range of the viral genes. It is also possible to fuse animal cells, which may involve undesirable transfer of viral genomes to new hosts[20,21]. Many of these experiments involve conjectural hazards comparable to those implied by the *in vitro* recombinant DNA technique.

But in these cases the experiments also probably carry only a low risk if they involve low risk viruses, since similar events probably occur in nature. Therefore we would like to propose that the entire area of recombinant DNA research should be re-evaluated. Experiments which are considered to involve real and proven risks should be prohibited at present. The transfer, by any method, of high risk viral genomes, potent bacterial toxins and antibiotic resistance to gonococci and streptococci fall into this category. Conjectural hazards which may or may not become real should rapidly be evaluated under secure conditions. Meanwhile *in vitro* recombinant DNA research can probably proceed in several areas including the transfer of low risk viral genomes to prokaryotic cells and the development of eukaryotic vectors from low risk viral genomes.

In closing, it should be emphasised that both mutagenisation and deletion of a multitude of genes in the laboratory have, to the best of our knowledge, never provided a selective advantage for an organism in the natural environment. Some genetic manipulation with plant cells may be an exception. It is necessary for the opponents of recombinant DNA research to provide examples of such selective advantage otherwise this debate will focus more on faith than science. □

Sulphur deposit account

R. A. Barnes looks at an OECD study on the transport of air pollutants over long distances

THE Final Report of the Organisation for Economic Cooperation and Development (OECD) study on the long range transport of air pollutants within north-west Europe was derestricted last week. It has its origins in the first European network of sites to monitor the chemical composition of precipitation which was established in Scandinavia in 1947. In the 1950s this was extended to other countries and became known as the European Air Chemistry Network. A first detailed analysis of the data, performed by Odén in 1968, showed that an area of highly acid precipitation (pH 3–4) located in the industrial heart of Europe was expanding from year to year. This finding was paralleled by the observation that rivers and lakes in southern Scandinavia were also becoming more acidic and so it was decided that a more detailed study of the origins of the acidity was required.

The Scandinavians in particular have expressed great concern that the increasing acidification of inland waters was causing the observed fall in fish populations and was also reducing forestry production. In their opinion, the sources of acid precipitation were sulphur dioxide emissions from the heavily industrialised countries of north-west Europe, particularly those from the UK. This latter view was based on the assumption that south-west winds prevailed and that the UK policy of making major industrial emissions from tall chimneys (the 'tall-stack' policy) to reduce nearby surface concentration—which affects about half the total UK emission—is particularly effective in encouraging the transport of pollutants over long distances.

The OECD programme began in 1972 with the aim of determining the relative importance of local and distant sources of sulphur compounds within European countries, special attention being paid to the question of precipitation acidity. Initially ten countries agreed to participate actively—Austria, Denmark, the Federal Republic of Germany, Finland, France, the Netherlands, Norway, Sweden, Switzerland and the United Kingdom—and in 1974 Belgium also joined. Although several surveys have already been made of air pollution fluxes and depositions within certain parts of Europe, the OECD study is the first comprehensive investigation of air pollution movement on a continental scale. Data analysis and interpretation, together with preparation of the final report, has been the responsibilty of the Norwegian Institute for Air Research.

The research programme consisted of observations based primarily on a network of sampling stations, and predictive modelling. In all, 76 ground level sites, sampling on a daily basis, were in operation at one time or another—8 in the UK and 23 in Norway. They were located, with moderate success, to represent rural conditions within a geographic region. Mean sulphur dioxide and sulphate aerosol concentrations observed at these sites ranged from about 20 μg m^{-3} and 10 μg m^{-3} respectively, close to the major source regions, to about 2 μg m^{-3} and 0.5 μg m^{-3} respectively in the remote areas of northern and western Europe. The higher of the sulphur dioxide figures would be approximately a factor of 5 less than in the source areas themselves, whereas the longer lived and slowly formed sulphate species would be more or less the same. The sulphate in precipitation data show a similar geographical distribution to the air concentrations, with values ranging from 5 to less than 1 mg l^{-1}. In some areas (for example south-west Scandinavia and Switzerland), however, where locally increased precipitation produces greater deposition than in surrounding districts, the pattern is modified. Strong acid in precipitation shows a distribution similar to that of sulphate but with notable differences in some areas. It seems to be due to both sulphuric and nitric acids in proportions of between 3 : 1 and 1 : 1.

Sector analysis

A sector analysis was performed on the surface measurements. Using 850 mbar (1,200–1,500 m altitude) trajectories they were allocated to six directional arcs and a mean value was calculated. The results show that high mean concentrations and/or depositions were not randomly oriented, but were directed towards the main areas of emission. When these emitting areas lie to the west of the receptor, concentrations are relatively low but aggregate depositions high. The low concentrations are probably a consequence of the higher wind speed and fewer stagnant, stable, conditions in westerly regimes, while the higher depositions would be related to the greater frequency of precipitation. In most parts of western Europe, higher concentrations are usually found in sectors directed towards the south and south-east, although these do not necessarily result in particularly high annual deposition totals. Winds from such directions are generally associated with a higher frequency of stagnant and stable conditions over source areas which would lead to the high concentrations, and with limited convective or frontal rainfall, wet deposition would tend to be limited. In south-west Norway, however, orographic precipitation in southerly and south-easterly winds, coupled with high sulphate concentrations, produces annual depositions in these sections comparable to those experienced in the westerly winds where precipitation is more frequent and plentiful.

Unfortunately, the sector analysis does not, in general, give a clear indication of which sources give rise to what fraction of the concentrations in a given sector. Because of its geographic position and relative isolation, however, an estimate can be made of the mean contribution of emissions in the British Isles to deposition in Norway and the Netherlands. In addition to the average 0.8 mg SO_4 l^{-1} and 25 μEq l^{-1} strong acid background in rainfall from Atlantic air, to which sources in North America seem to contribute, emissions in the UK and Ireland give rise to 1.0 mg SO_4 l^{-1} and 20 μEq l^{-1} strong acid. Mean concentrations at Norwegian sites due to other emission areas range up to 8.7 mg SO_4 l^{-1} and 140 μEq l^{-1} strong acid.

Several of the participating countries used instrumented aircraft to obtain data on above-surface concentrations of air pollutants. Flights were usually made under specific meteorological conditions and never at night or in cloud. The results confirm that under these conditions, sulphur compounds are normally transported in the lowest 2 km of the atmosphere, generally with a peak concentration a few hundred metres above ground level and a progressive decline above that height. The average mixing height under flight conditions was found to be 1,200–1,300 m, although individual vertical profiles varied considerably. The flights also showed that under certain conditions distinct plumes of pollutants existed several hundred kilometres downwind of major source areas.

Reference has frequently been made to 'episodes', when substantial amounts of wet sulphate deposition occur over a period of less than a day, without any attempt at a formal definition.

R. A. Barnes is at the Central Unit on Environmental Pollution in the UK Department of the Environment

Since such occasions, on which a substantial amount of the total annual wet deposition at a site may occur on one day, are likely to be of particular ecological significance, a working definition has been formulated: episode-days at a site are those with the highest wet depositions which, when summed, make up 30% of the annual total. An area is 'highly episodic' if 30% of its total annual wet deposition occurs on less than 10% of wet days. By these definitions parts of Norway, Finland, Sweden, Switzerland and Scotland are highly episodic with respect to sulphate. Sulphate episodicity has been shown to be relatively independent of precipitation episodicity.

Mathematical modelling was employed to obtain a more complete pattern of concentration and deposition in Europe. Estimates were made for 1974 only, and are unlikely to be the same for other years, especially in the case of wet deposition. One of the primary inputs to the models was detailed sulphur dioxide emission figures for the whole of Europe. For the 11 participating countries, man-made emissions were estimated to be 9 million tonnes as sulphur in 1973. Emissions of sulphur from other European countries were calculated to be 16 Mt in 1973 from much less reliable data. The total emission of approximately 25 Mt is approximately twice that in 1950, although some countries have contributed to the increase much less than others (the UK rise between 1950 and 1973, for example, was about 30%). Natural emissions were calculated to represent less than 10% of the man-made ones over the continent as a whole.

For use in the models, the national sulphur dioxide emission totals were allocated to a 127×127 km grid, using population and industrial statistics and simple seasonal adjustments made to arrive at emission figures representative of individual days. As a first aproximation 25% of the emission in any grid element was assumed to be deposited in that element.

Estimated budget for dry plus wet deposition of sulphur for 1974 (Unit: 10^3 tonnes of sulphur)[1]

Countries	Sulphur received	Sulphur emitted
Austria	300	221
Belgium	200	499
Denmark	100	312
Federal Republic of Germany	1,250	1,964
Finland	400	274
France	1,000	1,616
The Netherlands	150	391
Norway	250	91
Sweden	500	415
Switzerland	100	76
United Kingdom	1,000	2,883[2]
Czechoslovakia, German Democratic Republic, Italy, Poland and other areas	11,000	—

[1] Numbers are rounded to one significant figure and accurate to within about ±50%.

[2] Includes 80×10^3 tonnes of sulphur from Ireland.

Two models

A Lagrangian model was used to estimate the long range transport of sulphur on a continental scale and the so-called 'Trajectory Model' was employed to estimate the effect of any one country's emissions on the concentrations and depositions in any other country. Both functioned by considering emissions and depositions in individual grid squares and air movements according to 850 mbar (1,200–1,500 m) trajectories. Unfortunately, the choice of a coarse grid (which was necessitated by the low precision of emission data and trajectories, together with limited computing facilities) has caused the very steep gradients of sulphur concentration which exist in reality to be smoothed across 127 km^2. The models therefore only give a very general picture of concentration and deposition with a considerable degree of uncertainty on the accuracy of predicted values at any given point. The relatively coarse grid also made it difficult for one of the main objectives of the programme—the effect of local sources on concentrations and depositions—to be achieved.

The model estimates of daily mean sulphur dioxide and sulphate aerosol concentrations do not agree very well with observed data, correlation coefficients ranging from insignificant values to 0.6 and 0.4 to 0.8, respectively. The poorer correlation in the case of the shorter lived species (sulphur dioxide) reflects the greater effect of grid smoothing in this case. The correspondence between observed and calculated annual mean concentrations, however, at about 0.9 in both cases, is much better.

As would be expected, the estimated dry deposition pattern for sulphur in Europe strongly reflects the emission field with a maximum of 10 g m^{-2} y^{-1} in the major source areas and a minimum of about 0.1 g m^{-2} y^{-1} in remote regions. There is a high degree of qualitative agreement and quantitative similarity between the sulphur wet deposition fields estimated by each of the two models, and that prepared from observed data. To a certain extent, this agreement was to be expected, since all three approaches employ the same grid-smoothed precipitation map. The technique used for preparing the grid assumes zero precipitation more than 100 km from the nearest observation over land and 300 km over the sea. Thus, for grid elements in the centre of the North Sea, the precipitation is reckoned to be about 10% of that in eastern and central England. On a fairly arbitrary basis, it has been estimated that, for this reason, the contribution of British emission to sulphur wet deposition in southern Scandinavia has been overestimated by about 20%.

A regression of observed mean sulphate concentrations in precipitation against weighted mean values of calculated aerosol sulphate concentration, used by the Trajectory Model to estimate sulphur wet deposition due to one country in any other country, has shown that a good relationship ($r=0.9$) exists for Norwegian and Finnish data. The results suggest a natural background sulphate concentration of 0.8 mg l^{-1} in precipitation, a figure confirmed by the sector analysis. This regression has been used in the budget calculations for these two countries. A similar regression on data from the remaining countries, however, shows a much wider scatter ($r=0.36$) and an implied background of 2.0 mg l^{-1}. These results are probably a reflection of the influence of local sources in countries other than Norway and Finland, and would result in a great deal of the wet deposition in a given country being unattributed to any particular source. As a compromise, a relationship using all available data ($r=0.73$) and a 'background' of 1.2 mg l^{-1} is employed for all countries except Norway and Finland.

For several reasons, therefore, the Trajectory Model has not proved capable of estimating the dry or wet deposition in any one country due to emission in any other country to an accuracy greater than ±40%. Thus, the corresponding total (dry+wet) deposition figures are not accurate to more than ±50%. However, the estimates of the Trajectory Model do give a useful indication of the extent and magnitude of transboundary transport of sulphur compounds. Both models indicate that, within the area as a whole, about 50% of the sulphur emitted is dry deposited and 30% wet deposited. The balance leaves the region.

The OECD study has provided a first comprehensive insight into the long distance transport of air pollutants on a continental scale. It is far from definitive, but it has confirmed that sulphur compounds travel long distances in the atmosphere over Europe, and that the air quality in any one country is measurably affected, in a very complex fashion, by emissions in another. Much more precise and detailed work is required if the phenomenon is to be fully quantified, the report itself listing a number of facets which require further investigation. These could be taken into account by an Economic Commission for Europe study, at present in a planning stage. □

Five-year stretch

The USA and USSR have agreed to another five years of scientific cooperation. Colin Norman reports from Washington

WHEN former President Richard Nixon travelled to Moscow in May 1972, he came away with a clutch of agreements for Soviet–American scientific exchange programmes which symbolised the new era of detente. Since then, the warmth of detente has been chilled by disagreements over arms control and human rights issues, but the scientific exchange agreements have proceeded apace. Last week, after a cordial meeting between Soviet and American officials in Washington, the agreements were renewed for another five years.

The renewal was negotiated at a high-level meeting of scientific delegations led by Dr Frank Press, President Carter's science adviser, and Academician V. A. Kirillin, Deputy Chairman of the USSR Council of Ministers, and chairman of the State Committee of the USSR Council of Ministers for Science and Technology. Press later described the meeting as "extremely cooperative, upbeat all the way". To underline the political importance attached to the agreements, President Carter met Kirillin for a widely publicised discussion shortly after the ritual signing ceremony.

This outbreak of cordiality in the midst of Soviet–American ill-feeling lends itself to a number of interpretations; the most widely touted is that the Soviets are willing to put aside their differences to continue with exchanges from which so far they have benefited greatly, while the Americans are eager to demonstrate that the Carter Administration's stand on human rights need not jeopardise mutually beneficial arrangements between the two countries. In any case, extension of the agreements was never seriously in doubt.

In preparation for last week's meeting, however, Press commissioned a review of how the exchanges have operated so far, and as a result there will be some changes in the way the arrangements will work in future. The review was carried out by a committee of the National Academy of Sciences, headed by Richard Garwin, a respected physicist who works for IBM. The Garwin panel interviewed scores of scientists who have participated in the exchange programmes, and its central conclusion was that the agreement should be renewed because of "the positive benefits and real interaction evident in some of the projects under the agreement, [and] the intangible and unevaluated (but widely felt) non-substantive benefits commented upon by the participants". Nevertheless, the Garwin panel pinpointed a number of problems.

The science and technology agreement is in fact only one of about a dozen exchange pacts negotiated as a result of Nixon's May 1972 Moscow summit meeting (separate agreements exist for cooperation in space, environment, energy, medicine and other areas), but it is widely regarded as the most important. It established joint programmes in such fields as chemical catalysis, physics, forestry, the application of computers to management, electrometallurgy and science policy. Some 250 American scientists have participated and the cost to the US treasury has been about $13.2 million over the five-year period.

The Garwin panel reported that progress has been decidedly mixed. In the physics programme, for example, "no exchange or substantive interaction has taken place thus far", while as a result of exchanges in the electometallurgy programme, "familiarity with differences in approach and perceptions in solving technical problems in the USSR has stimulated a considerable amount of rethinking of technical approaches in the US".

There have also been a number of problems common to most of the programmes. For example, the Garwin panel noted that although virtually every participant interviewed emphasised the helpfulness and warmth of individual Soviet scientists at the working level, there appear to be "layers of stifling bureaucracy which enforce a rigidity in the interaction which very much diminishes its value to the US and to the USSR". As evidence of such stifling bureaucracy, the panel cites inflexibility in travel arrangements for US scientists visiting the Soviet Union and lack of notification of the time, date, or place of arrival of Soviet visitors to the United States.

But the problems do not lie entirely on the Soviet side of the exchanges. The Garwin panel noted that US delegations are often ill-prepared before they visit the Soviet Union. There is little interaction between participants in different exchange programmes, and American scientists are seldom briefed on Soviet research and development policies and practices.

The Garwin panel recommended that a small, permanent bureaucracy should be established in the United States government to plan and coordinate the exchange programmes and to prepare US scientists for their visits to the Soviet Union. According to one official involved in last week's talks, such a group is likely to be established soon, probably in the National Science Foundation.

A frequent complaint raised in the United States, particularly among conservatives, is that the flow of information from the scientific exchanges has been virtually a one-way street, from West to East. The argument is that since the Soviet Union lags behind the United States in many fields, it is eager to use the exchanges as a conduit for American technology. The Garwin panel did not specifically address that concern, though it noted in its report that participants in the programme frequently point to "significant political and cultural benefits in addition to the relatively few citations of benefits to US science and technology". Such intangible benefits should also be weighed in assessing the overall impacts of the agreements, the panel suggested.

Nevertheless, the Administration is understandably sensitive to charges that the exchange agreements are resulting in a significant drain of technical information from the United States, and according to one official familiar with the programme, greater attention will in future be paid to securing a better balance of information flow throughout the programme.

Press said that some of the concerns raised by the Garwin panel were brought up during the negotiations last week, and the Soviet participants were willing to discuss ways of smoothing future arrangements. At one point, Kirillin said that if problems arise, he and Press would communicate directly by telephone to iron them out. Asked whether human rights problems were mentioned during the talks, Press said that they were not.

For their part, the Soviets seem anxious to press on with the exchanges, while the Carter Administration seems to feel that for an outlay of only about $2–3 million a year, the agreement is an inexpensive way to foster better relations. ☐

Correction

In last week's item about Czechoslovakia a line crept in to confuse the meaning of a sentence. Dr Zdenek Mlynar's dismissal was for being a member of the campaign known as Charter 77. Our apologies.

USSR

Professor Veniamin Levich was dismissed from his post at Moscow University in 1972 as a result of his application for a visa to emigrate to Israel. He had done definitive work in a number of fields including electrochemistry and physicochemical hydrodynamics. A number of Soviet scientists working in related fields were invited to attend a conference in Oxford to celebrate his 60th birthday. All declined. Extensive extracts from a letter explaining the Soviet attitude, and from a reply from Sir Derek Barton, Chairman of the Conference Committee, and Professor D. B. Spalding, Conference Organiser, appear below

Dear Colleagues,—Over the past few months many of us have received invitations to an international conference in mid-July on "Physical Chemistry and Hydrodynamics" organised in connection with the 60th birthday of Professor V. G. Levich, corresponding-member of the USSR Academy of Sciences. For a number of reasons that are outlined below we had not intended to reply to the invitations. However, since our silence could have been misunderstood and misinterpreted, we decided to explain our attitude in this letter. . . .

You will agree that it is most unusual for a scientific conference marking the 60th birthday of a Soviet scientist, a corresponding-member of our Academy of Sciences, to have been organised and to be held in another country, without any prior consultation or agreement with organisations representing Soviet science. There is no denying that there are many major scientists in our country whose work has received universal recognition in the world. A number of them have won the Nobel Prize. But none, to our knowledge, has won such attention as Professor V. G. Levich. That leads us to believe that in this case it was not Professor Levich's scientific services that prompted this attention. Scientific services alone would not warrant it. Therefore, there must be some other reason. Apparently, it is because over the past few years Professor Levich has been busy besmirching his country, clearly to the detriment of his scientific work.

We cannot, naturally, exclude the possibility that many of the participants in the conference, and perhaps its organisers as well, honestly think there has been prejudice in Professor Levich's treatment by the leaders of his Institute, of the Academy of Sciences and perhaps also other bodies in our country. Maybe that prompted them to take such an unusual step in what they regard as support or defence of Professor Levich. But even if that were the case, it would be interesting to know their source of information.

Why, when inviting us to the conference, did nobody ask for our opinion? Why was it decided to accept implicitly the information received from Professor Levich, while the views of those who worked with him and who could provide a more objective assessment were ignored? We, consequently, feel justified in concluding that our point of view does not interest the organisers of the conference, that they are not interested in the truth of the matter, and that the entire Levich affair is merely a peg on which to hang efforts to set the scientific world in the West against the Soviet Union.

This conclusion is inescapable. It is confirmed by the wide circle of persons invited to the conference. Hundreds of people in our country, and maybe even more, have received invitations. Never before, not even when jubilees of the most outstanding Western scientists were marked, did that happen. What is significant is that many of the recipients of invitations never had anything to do with the theme of the conference, let alone the field of research in which Professor Levich works or science in general. So what does all this mean?

USSR version on the right

. . . We feel that the whole affair of marking Professor Levich's birthday can do nothing but harm to international cooperation. If the organisers of the conference sincerely desire to strengthen international cooperation, we cannot but ask—with whom? With those who, like Professor Levich, believe for one reason or another that they have been unfairly treated and have become openly hostile to our country, or with the vast majority of scientists who really represent Soviet science and are deeply loyal to our country?

We firmly believe that in deciding to convene this conference its organisers were concerned not with promoting international cooperation between scientists, but with using Professor Levich's 60th birthday to set public opinion against our country . . .

Ya. Kolotyrkin, K. Gorbunova, B. Kabanov, V. Losev, N. D. Tomashov, N. Shumilova, V. Dmitrenko, N. Lidorenko, S. Karpachoy, J. Matulis, D. V. Sokolsky, J. Stradins. Y. Delimarsky.

Dear Colleagues,—We have been gratified by the interest which you have shown in the Levich Conference. Other Soviet scientists have written in answer to the invitations; some have been friendly, and others less so; but none have set out their views at such length. Your courtesy is much appreciated. . . .

. . . We remark with pleasure that recognition of Professor Levich's contributions to science is not something which divides us.

Concerning paragraph 3 [2 above], we do agree that the holding of this conference in Oxford rather than Moscow is somewhat unusual. Had the USSR Academy of Sciences announced that it intended to celebrate the occasion suitably, the Oxford Conference might not have been convened. Were there any such intentions? Our enquiries revealed none.

We do not know how to compare the attention accorded to the Levich Conference with those celebrations which other scientists have enjoyed; but it is gratifying to the Conference secretariat to know that their publicising efforts have been successful. Our own belief is that the popularity of the conference has much to do with the high importance of physico-chemical hydrodynamics. This subject is, for many scientists, inevitably linked strongly with the work of Levich.

Your paragraph 4 questions the sources of information, and the motives, of the organisers and sponsors of the conference. Our information sources are too numerous to list comprehensively; so examples must suffice. The way in which its Soviet distributors excised Levich's name from an article by Professor Parbury Schmidt (see appendix) is documentary proof of a kind. We have seen the letter from Academician Frumkin relieving Professor Levich from his position, solely because he had exerted his legal right to apply for an exit visa. We have corresponded and held discussions with numerous Soviet scientists, officials and ordinary citizens. . . .

When, we ask you, was Professor Levich last permitted to conduct a seminar in his Institute? When will that permission next be given?

Concerning motives, it is necessary to be blunt: your "inescapable conclusion" is ludicrous; "to set the scientific world in the West against the Soviet Union" is as remote from our intentions as it is beyond our powers. We earnestly ask you to give weight to an alternative possibility, namely that the motives of the sponsors and organisers are commensurate, in probity and good sense, with their scientific attainments and with the dignity of their offices. Please consider well their names; then ask yourselves again: *can* your inescapable conclusion be correct? We would assure you that if any scientist of the standing of Levich, in any other country of the world, were treated in the same way, our involvement would be exactly the same.

In paragraph 5, you express uncertainty as to whether the effect of the conference on international cooperation in science will be good or bad; and you ask with whom cooperation is intended by us. The answer to the second question is: we hope to cooperate with *you*, and with your colleagues in the USSR; that is why we sent you invitations, and that is why the conference publicity has been kept entirely free from words which might embarrass you.

As to the effect of the conference on relations between Western and Soviet scientists, this depends greatly upon you. We have made plain our equal concern for science and for freedom of movement in all countries. We have disclaimed all provocative intent; and, incidentally, we have provided your government, if it wished to take it, with an opportunity gracefully to extricate itself from an awkward situation . . .

Yours sincerely,

Derek Barton, Brian Spalding

EEC

Research: no stop ahead?

If the words of the European Commission are anything to go by, the EEC's involvement in science and technology needs to intensify. Whether or not the Nine member countries of the Community automatically allow such a development is increasingly open to doubt, but the Commission's ideas and hopes for the next few years are now contained in a document which it approved at the end of last month and sent to the Council of Ministers and European Parliament for their consideration.

The document, *The common policy in the field of science and technology,* is in three parts. The core, appropriately enough, is the middle part, and this details the guidelines which the Commission has adopted for the next phase—that is, 1977–80—of Community science and technology policy. With ten chapters and two annexes, it is a detailed if wordy conspectus directed not only at the Council but also "to all those affected by the European research policy". According to brief final remarks, key areas of Community concern—"such as economic competitiveness, secure energy and raw material supplies and the preservation of a humane social and physical environment"—are becoming "more and more dependent" on a common science and technology policy.

The earlier part of the document contains three draft texts which the Commission proposes that the Council should adopt. One is a resolution on the guidelines that make up the middle part This says that coordination of R&D shall be "gradually developed and intensified"; that special attention should be paid to the European Science Foundation's activities; that proposals be made for the better use of R&D results; and that a full review of EEC science activity be undertaken by the end of 1979.

The second text provides for a decision on promotion of industrial R&D projects. This would be done through financial assistance to small- and medium-sized firms cooperating in the sphere of innovation. The third text, which reflects the Commission's feelings that research in forecasting and assessment is essential, provides for a decision on a five-year research programme costing 4.4 million units of account and employing 10 staff. The aim of the programme would be "to contribute to the definition of long term R&D objectives and priorities".

The final part of the document, from which the accompanying graphs are taken, analyses public financing of R&D and has 15 graphs and four tables that summarise the main trends in the Community over the past six years. They belie the promise of the guidelines. According to the document, there is a general stagnation in R&D funding in all Community countries, an increasing gap between the Nine and the USA, and a gap between collective Community funding of R&D and funding within the individual member countries themselves. Some 64% of Community R&D funds is concentrated on energy; health takes 15–16%, and industry 12–14%.

JET

Is it enough?

A new development came last week in the saga over JET. Chris Sherwell reports

In what in the absence of confirmation otherwise looks suspiciously like an embarrassing climbdown, Britain last week withdrew one of its last remaining sanctions over the controversial decision on where to site the European Community's Joint European Torus (JET) fusion project. The Council of Foreign Ministers is due to make a final choice between Culham in Britain and Garching in Germany—unless it can come up with a third site as a compromise—at a make-or-break meeting later this month.

Britain has hitherto kept a reserve on the expenditure of about £145 million for the 1977–80 joint research programme of the Community, even though the research programme has itself long been agreed, as a bargaining chip over JET. The official reason has been that the research programme contains a good deal of fusion work, and Britain did not want to see decisions taken "piecemeal". But an announcement last week from Brussels, which was welcomed by the European Commissioner concerned, Dr Guido Brunner, disclosed that Britain had withdrawn her reserve "in the interests of the Community", but apparently in recognition that it had become more of a hindrance than an aid to progress on JET.

Whether the move will help Culham get JET is another question. Brunner spoke of "improving the climate of decision-making", but Britain's handling of matters like these in the past does not exactly augur well. At the energy ministers' meeting in March, for example, a concession over a scheme involving Euratom loans turned out to be rather costly when there was little of the expected progress on another important matter, the minimum safeguard price for oil. On that occasion too Britain's obstruction had by then blackened its reputation. The same could happen again over JET.

Moreover, the new concession may not be enough. In the view of some, a satisfactory decision on JET was possible when the research ministers met in March. The argument is that the political price Britain has to pay to win JET increased at that meeting when, as presidential chairman, she mishandled things and failed to call for a vote—a vote which, it is widely recognised, would then have gone in Garching's favour. ☐

BRITAIN

● Public fears in the developed world about nuclear power as no less real for the fact that the hazards of overeating, alcohol, cigarettes and automobiles may be greater. Among those fears the horror of radiation looms large, and if the risk posed by nuclear war is discounted, a nuclear reactor accident must be a favourite worry. The UK National Radiological Protection Board (NRPB) has reviewed the data describing the effects of radiation exposure on a population precisely in order to assess the biological consequences of the accidental release of radioactivity from a reactor. It published the findings last week*.

Information on the effects of radiation in man was derived from various studies—of individuals exposed to the atom bombs dropped on Hiroshima and Nagasaki, of Marshall Islanders contaminated with fall-out, of accident cases in the nuclear industry, and of patients treated by radiotherapy. This was supplemented with data obtained from experiments on animals. Exposure to radiation was presumed to occur in various ways: acute external exposure of the body, whether from the passing cloud or from contaminated ground; inhalation of activity from the cloud and ground and from contaminated food and water; and relocation of incorporated radionuclides within the body.

Depending on the radiation dose, an exposed population is expected to suffer both early ("acute") and late physical damage. Acute effects are minimal below a certain threshold dose. Above that dose, cell membrane damage allows fluids and electrolytes to leak out of the vascular system, and stem cells lose their reproductive capacity, meaning that normal functions can be impaired. The main late effect, cancer, has no threshold; damage to blood vessel linings, hyperthyroidism, cataracts and sterility may also occur.

The report suggests a threshold of about 200 rads (low LET), below which no deaths would occur, for irradiation of the bone marrow. For the lower large intestine a threshold of about 2,000 rads (low LET) is accepted, where the dose is received in the first seven days after exposure and the probability of death covers a one-year period. Pulmonary morbidity is not expected below a threshold dose over one year of 2,500 rads (low LET).

The report also details estimates concerning late effects. For death from leukaemia it gives a risk coefficient, in cancer deaths per 10^6 man rads (low LET), of 20. Other figures are: cancer of the lung, 20; bone, 10; liver, 10; gastrointestinal tract, 20; breast, 20; thyroid, 5; and all other cancers, 20. The total risk coefficient is 125. The estimates, the report says, are "considered adequate". As for hereditary disease, the report predicts a total of 57 serious cases per 10^6 man rads (low LET), of which 15 and 9 would appear in the first and second generations respectively.

● Britain and the USA are to collaborate on coal research. The chairmen of the UK's National Coal Board (NCB) and the USA's General Electric Company agreed last week to exchange technical information on ways of using coal more efficiently, particularly as an energy source. It is hoped that exchanges on coal gasification, liqueaction, fluidised combustion and the production of metallurgical fuel will eventually lead to jointly run research projects.

British technology is already being used in one US coal gasification project. Work on a gasification process, done at the NCB Utilisation Research Laboratories in Surrey in 1972, is to be incorporated into a recently-approved \$24-million design project which should eventually lead to a \$334-million plant for Illinois to extract gas and low sulphur oil from coal. The Canadians too are using British expertise in coal. The British partnership of the NCB and Woodall-Duckham Ltd is under contract from British Colombia Hydro and Power Company in Vancouver, Canada, to study the feasibility of designing a demonstration plant for cleanly and efficiently producing electricity and gas from Canadian coal.

Coal, of course, is the less controversial key to Britain's plans to bridge the so-called 'energy gap' in the 1990s (the more controversial one is nuclear power). But last week the chairman of British Gas, Sir Denis Rooke, injected his own element of controversy by dismissing suggestions that there will even be an energy gap at that time. The technologies were being developed, he said, to make substitute natural gas from coal or oil. The energy minister with responsibilities for gas said Britain was already looking to the time when it would have to rely on SNG.

● It is a commonly expressed view that Britain has not been making the most of its professional engineers over the past few years, and that little has been achieved in improving the engineer's lot, especially in manufacturing industry. Now the government has announced a Committee of Inquiry into the engineering profession. Sir Monty Finniston, formerly at the British Steel Corporation, will chair it.

The committee will look at how British industry could better use engineers of varying educational achievement. It will also examine the part engineering institutions could play in relation to the education and qualification of engineers at professional and technician level; the possibility of statutory registration and licencing of engineers in the UK; and the engineering profession in other countries, especially in the EEC. The committee's fifteen or so members have yet to be chosen, but they are expected to convene by the autumn.

Critics have said the inquiry might delay urgently needed changes. But the Secretary of State for Industry, Mr Varley, hopes that the inquiry will not be "unduly prolonged" (it is expected to last 18 months). And if the committee feels that some of its findings deserve urgent attention, it will probably be able to produce interim reports. One question is whether the committee will recommend the establishment of a body to control academic standards and entry to the profession. Professional engineers would then be organised in a similar way to the medical profession, and the new body would be analogous to the General Medical Council.

FRANCE

Mixed fortunes

French nuclear fortunes followed a mixed path last week. A correspondent reports

THE French Cabinet was apparently expected to discuss nuclear issues last week, but reportedly failed to do so. The minor controversy caused by a leak of uranium hexafluoride gas at a plant in southern France couldn't have helped. But there was some glory to bask in too—the signing of a cooperation agreement with West Germany covering fast breeder reactors.

The agreement is not unprecedented, being in line with an arrangement reached in Nice in February last year which involved the two countries pooling risks over both breeders and high temperature reactors. Given the new US policy, however, its timing may be awkward.

A key feature of the latest agreement is the exchange of information on fast breeder R&D over a 20-year period. This involves the French Atomic Energy Commission (CEA) on the one hand and Interatom, a subsidiary of the German company Siemens, and the Nuclear Research Centre of Karlsruhe on the other. Reports suggest that the French will maintain their fast breeder research effort at existing levels, at about FF400–500 million annually—the Germans pitch in a similar sort of amount —but that both sides are hoping for more efficient use of the funds.

Commercialisation of the fast breeder becomes the object of a new French-dominated company established under the agreement known as Serena. This allows the participation of Belgian, Dutch and Italian interests along with the principal partners from France and Germany.

Paralleling this development is one concerning French uranium supplies. In a deal with a South African corporation, the CEA is reportedly to receive 900 tonnes of uranium oxide over 10 years in return for funding the capital investment programme of the mine which will produce it. ☐

BANGLADESH

Energy projection

The Bangladesh government recently received a report on its energy prospects. A report from M. Kabir

OVERALL demand for energy is increasing with population growth and with greater industrialisation, and the government of Bangladesh has felt the need for a major study to guide long term policy and advise on specific projects that should be implemented over the next 5 to 10 years. Responding to a government request, the United Nations Development Programme (UNDP) agreed to support and finance through the Asian Development Bank a study involving Canadian, American and Italian firms. This began in mid-1973.

An 8-volume draft of the final report was submitted recently. It considers the energy sector as part of the larger economic system of Bangladesh, attempting to identify interdependence both within the energy sector and between this and other sectors of the economy.

In Bangladesh, about 90% of the people living in the villages consume about 80% of the total energy. But only a small part of total energy requirement for a massive population of 75 million is supplied in commercial form as electricity, gas or petroleum products. Most derives from the burning of traditional fuels, for which estimation of the energy equivalent is difficult given the lack of statistics.

The existing electric power system consists of two separate zones, the East Zone and the West Zone, divided by the river Jamuna. The most recent year for which data were available for the study was the financial year 1973–74, and in this period generation for public supply amounted to some 1,260 GWh—980 GWh in the East Zone and 280 GWh in the West. In addition there are facilities directly owned by users, known as 'captive power', generation of which in 1973–74 was about 460 GWh, the bulk of it in the East Zone.

In assessing demand a major effort was made in the study to project the likely growth of agriculture. That meant considering the speed with which farmers will adopt new technologies, for example, but also examining the institutional framework within which development occurs. An analysis of demand based on various 'scenarios' in a macro-economic model yielded various projections anticipating population, agricultural production and production in other sectors. The 'mid-demand' scenario, which was adopted as an appropriate basis for energy planning, projects 3,971 GWh for the East Zone and 2,292 GWh for the West. The equivalent figures on the 'high-demand' scenario were 5,004 GWh and 2,608 GWh. ☐

CHINA

Conference plan

A NATIONAL CONFERENCE on science and technology is being organised in the People's Republic of China, according to Professor Ren Ci-gong of the Applied Physics Laboratory at Johns Hopkins University. He left China on 30 June after an extended 2½-month tour. Interviewed by reporters in Hong Kong, he said its scale would "greatly exceed anything that we can imagine". During his tour he had come to know of many regional conferences, attended by specialists as well as representatives of the broad mass, and these served as preparations for the planned event.

The news accompanies intense activities in China within the past seven months both in matters of science policy and others involving modernisation of agriculture, industry, communication and defence. On the international level, a Chinese delegation which included such leading scientists as Chien San-chiang of the Peking Institute of Atomic Energy and T. C. Tung of the Institute of Zoology has just returned from a visit to Australia. And last month a team of American scientists headed by Philip Handler, President of the US National Academy of Sciences, went to China.

One of the aims of these exchange visits is no doubt to lay the path for further increases of mutual understanding and cooperation in the field of the natural sciences between the Chinese and other peoples. A long article appeared in *The People's Daily* (Peking) on 30 June signed by the 'Theoretical Group of the Academia Sinica'. In it the validity of a previously published document, "Summary of Reports from the Academia Sinica", was re-affirmed. This was frequently referred to in the campaign to criticise Teng Hsiao-ping, with whose explicit approval it was originally released for internal circulation among state departments. Its content is now widely known and may prove to be a good indication of China's science policy now that the so-called Gang of Four and their followers have been removed from the leadership.

T. B. Tang

IN BRIEF

Azbel in Israel

Mark Azbel, who for the last 2½ years has been running the Moscow 'Sunday seminar' for refusnik scientists, arrived in Israel last week. He said the recent closure of the seminar was not a condition of his obtaining an exit visa, and that he was confident it would reopen shortly.

German report

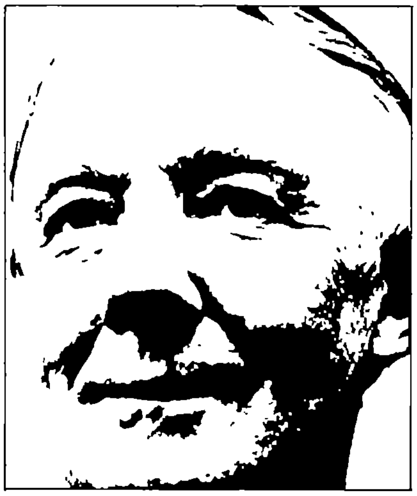
Professor Heinz Maier-Leibnitz, president of the Deutsche Forschungsgemeinschaft (DFG) has told of the continuing effect of financial cutbacks on Germany's research effort. Writing in the 1976 annual report, published at the end of last month, he says the "awareness of being at the mercy of something arbitrary in [research] promotion, wherever it comes from, and not to know any more whether a good plan will even be welcomed, easily leads to discouragement and bitterness".

Of the DM646.1 million the council had at its disposal last year (an increase of DM26.1 million on 1975), DM367.6 million came from the Federal government and DM269.9 million from the Lander.

European scrutiny

Well over a year after welcoming the suggestion that other House of Commons Select Committees apart from the existing Committee on European Legislation should consider proposals coming from the European Commission, the Select Committee on Science and Technology has decided to "consider the merits of EEC instruments falling within their order of reference". But the committee's special report announcing the decision, published last week, indicates the sort of fears about divisions of responsibility that may have caused the delay. Such work, the report insists, "cannot supplant the examination of such instruments by parliamentary representatives in the Energy and Research Committee and other appropriate Committees of the European parliament".

Acid rain



KENNETH MELLANBY

Air pollution has both local and international effects. Smoke and dust are usually urban problems, less serious the further one moves from their source. Fluoride, from brickworks and aluminium smelters, seldom causes damage beyond a radius of fifteen kilometres. But sulphur can be transported for hundreds of kilometres, over frontiers and oceans, and may cause international disagreements. It is well known that scientists in Norway and Sweden complain that sulphur emissions from Britain, Germany, Czechoslovakia and Poland have turned their rain and their rivers acid, harming freshwater fisheries, and possibly reducing growth in their coniferous forests. Many people have the impression that the industrial countries have developed a technique for keeping their own air relatively clean and at the same time causing gross pollution to harm the innocent Scandinavians.

It is true that, though there has been little decrease in the total emission of sulphur by industry and from domestic heating in Britain over the last twenty years, levels of sulphur dioxide, SO_2, in our cities have fallen as the gas has been increasingly discharged from high chimneys. This can be shown by the way the disease 'black spot' has returned to damage roses in urban gardens, where previously the fungicidal properties of the air kept it in check. But though the sulphur is certainly more widely dispersed, the bulk of it remains near to its source. British or German air is much more heavily charged with sulphur than that which crosses the sea to Norway and Sweden. British rain is generally acid. Even in rural Cambridgeshire measurements of pH 4 and lower are common; some 70 kg of sulphur is deposited on average on every hectare of Britain, and more than 20 kg in the most rural farming areas. The amounts deposited in Scandinavia are much lower. Yet damage in Britain is rare, and widespread in Norway and Sweden. The situation is clearly complicated.

In Britain most of the sulphur polluting the atmosphere is gaseous SO_2. Even in the cleanest areas annual average levels of $20\,\mu g\,m^{-3}$ are recorded. These are generally believed to have no harmful effects. None have been detected with crops or animals, and even foliose lichens, plants known for their extreme sensitivity to sulphur, flourish. In southern Norway, SO_2 levels are seldom as high as $5\,\mu g\,m^{-3}$, and, as we would expect, lichens grow well. By British standards, the air is remarkably pure. The SO_2 hardly seems to be the villain.

The main cause of acid rain seems not to be SO_2 but sulphate. In Britain amounts of sulphate are, in comparison to SO_2, low, and probably of little importance. In Scandinavia most of the airborne sulphur is present as sulphate, much derived from SO_2 produced by European industry and transformed during the period of passage north. This is washed out by the heavy rainfall. As already mentioned, the rain is actually less acid than that falling in Britain, and the total amounts of sulphur are generally small (less than 10 kg per hectare). Why then should there be all this fuss?

There are two main reasons. First, most water in Britain is well buffered, and it and most soils can neutralise most of the (comparatively large) amounts of sulphur pollution. Most Scandinavian freshwater is very 'pure' with little buffering power, so a little additional acid can greatly reduce the pH Also much rain is stored as snow for up to six months; when it thaws the pollution of half a year can be suddenly discharged.

There is no easy solution. Industrial countries can reduce levels of sulphur emission sufficiently to eliminate damaging pollution within their own borders, but will find it difficult to prevent the small fractions of their emission which escape overseas from damaging the rivers of Scandinavia. It is ironical that this sulphur can also contribute to agricultural productivity. Many Scandinavian soils are sulphur deficient and to optimise crop yields this element must be added as a fertiliser unless adequate amounts are deposited from the atmosphere. What is pollution for the fish may be an essential growth factor for the cereals.

Preparing scientific papers

Sɪʀ,—A great deal of time is wasted because young scientists submit papers for publication in an unacceptable form. There are many good books on the market on the preparation of scientific papers, but few specific examples as to how an unacceptable manuscript can be transformed into one acceptable by leading scientific journals. By a lucky chance (and completely legally) I was able to obtain a copy of such a manuscript with the referees comments and a model re-written version, from the editorial files of a leading geological journal, and I pass this on in the hope that it will be of value to authors in preparing papers for publication.

Columnar Rock Structures from an Antique Land

Referees' report:
manuscript 19705B/76: P. B. Shelley

Manuscript as submitted:

Ozymandias[1] by P. B. Shelley[2]

I met a traveller[2] from an antique land[3]
Who said: Two[4] vast[5] and trunkless legs[6] of stone[7]
Stand in the desert.[8] Near them[9] on the sand[10]
Half sunk, a shatter'd visage lies whose frown
And wrinkled lip and sneer of cold command
Tell that its sculptor well those passions read
Which yet survive stamp'd on these lifeless things,
The hand that mock'd them and the heart that fed;[11]
And on the pedestal[12] these words appear:
"My name is Ozymandias, King of Kings.
"Look on my works, ye mightly, and despair."[13]
Nothing beside remains[14]; boundless[15] and bare
The lone and level sands[16] stretch far away.

Referees' comments

[1] This title is quite inadequate. Includes no keywords. See suggestion below.

[2] Since this paper appears to be based on field observations by another geologist, we suggest joint authorship would be appropriate.

[3] Specify.

[4] This is the only quantative statement!

[5] Not specific enough. The authors should give dimensions in SI units. (Unless "vast" is a class in some sort of grade-scale, in which case, the reference to this scale should be given.)

[6] Have alternative hypotheses been considered? Earth pillars? Basalt columns? Ant hills?

[7] Surely identification of rock type with appropriate analyses could be provided here?

[8] Give co-ordinates.

[9] Specify distance. A photograph (giving scale) would help here.

[10] Give granulometric analysis, and preferably some scanning electron microscope photographs of grain-surface textures. These don't actually prove anything, but are decorative and keep SEM operatives in employment.

[11] This fanciful and speculative section could well be omitted.

[12] This is the first we have heard of a pedestal!

[13] While it may be worth-while to record the defacement of an interesting exposure, it is not necessary to quote the words. (Since they are in English, they are obviously of no archeological interest. Presumably graffiti sprayed on by a tourist).

[14] Rather dogmatic. Better: "No other rock exposures *were observed*".

[15] Inappropriate hyperbole. The approximate extent of the desert should be stated, if relavent.

[16] Unless this is a windless desert, surely a sandy desert should show dune formation? If actually level, perhaps in fact it is a stony desert?

General remarks Although some interesting observations are recorded, we cannot recommend publication in the present form. For one thing, the paper is far too short. For another, the authors have inexplicably left out any mention of plate tectonics! For the guidance of the authors, we give below a summary of the kind of re-written and expanded paper which might be acceptable. We have had to supply necessary missing data arbitrarily; it is, of course, up to the authors to substitute the correct data.

Suggested re-written manuscript (summary)

Twin limb-like basalt columns ('trunkless legs') near Wadi Al-Fazar, and their relationship to plate tectonics

Ibn Batuta[1] and P. B. Shelley[2]

In a recent field trip to north Hadhramaut, the first author observed two stone leg-like columns 14.7 m high by 1.8 m in diameter (medium vast, ASTM grade scale for trunkless legs) rising from sandy desert 12.5 km southwest of Wadi Al-Fazar (Grid 474 753). The rock is a tholeiitic basalt (table 1); 45 analyses by neutron activation technique show that it is much the same as any other tholeiitic basalt (table 2). A large boulder 6 m southeast of the columns has been identified as of the 'shattered visage' type according to the classification of Pettijohn (1948, page 72). Granulometric analysis of the surrounding sand shows it to be a multimodal leptokurtic slightly positively skewed fine sand with a slight but persistent smell of camel dung. Four hundred and seventy two scanning electron photomicrographs were taken of sand grains and 40 are reproduced here; it is obvious from a glance that the grains have been derived from pre-cambrian anorthosite and have undergone four major glaciations, two subductions, and a prolonged dry spell. One grain shows unique lozenge-shaped impact pits and heart-like etching patterns which prove that it spent some time in upstate New York.

There is no particular reason to suppose that the columns do not mark the site of a former hotspot, mantle plume, triple junction, transform fault, or abduction zone (or perhaps all of these).

Keywords: plate tectonics, subduction, obduction, hotspots, mantle plume, triple junction, transform fault, trunkless leg, shattered visage.

The laetrile question

Sɪʀ,—When Thomas H. Jukes came to witness our laetrile hearings (19 May, page 201), he missed the main battle and reported only the smokescreen. As an American, a scientist and a nonbeliever in laetrile, let me give an alternative view.

Support for freedom to use harmless drugs is no more a "crushing defeat to science and rationality" than is freedom to seek medical miracles through an established religious faith. The laetrile controversy brings into play three considerations:

- History is replete with examples where the consensus of established scientists was wrong.
- There is considerable resentment of the wealth that medical doctors extract by virtue of their monopoly control over the keys to life and health; prescriptions, laboratories and the like.
- Many people in the United States strive for freedom from excessive government; we seek a compromise between freedom and control in which individuals can pursue happiness as they see fit.

The laetrile question strikes all three chords. "Shall the government grant to doctors the exclusive right to dispense or withhold a drug which they believe to be harmless?" Would Jukes turn people away from Lourdes? Surely the answer is no, and just as surely the answer is no defeat for science.

Yours faithfully,
Tʜᴏᴍᴀs A. Cʀᴏғᴛ

Adenovirus amazes at Cold Spring Harbor

from J. Sambrook

The XLII Cold Spring Harbor Symposium on Quantitative Biology, entitled Chromatin, was held on 1–8 June, 1977. New insights into the ways in which gene expression is controlled in adenovirus were reported at the symposium and are described below.

IF success were exactly proportionate to effort invested, our understanding of the mechanism of gene expression in eukaryotes would be virtually complete. Unfortunately, despite intensive investigations for a number of years, our ignorance remains almost total. In part, this frustrating situation stems from the technical difficulty of analysing the expression of genes which may be represented only once in a huge and complex genome. However, the continuing dearth of useful mutations in control regions and the failure to reconstitute *in vitro* systems in which synthesis of mRNA or its precursors is initiated have also been strong contributing factors.

Despite these difficulties, there is circumstantial evidence of several sorts to indicate that extensive control of gene expression occurs at the level of mRNA synthesis. For example, mRNAs which code for specific differentiated products are detectable only in those cells which are committed to make those products. Thus, globin mRNAs are found only in reticulocytes, ovalbumin mRNAs only in cells of the oviduct and so on (see *Nature, News and Views* **267**, 203; 1977). Two competing theories have been used to explain how such gene regulation may occur. The first, based on experience with prokaryotic systems proposes that different regions of the cell's genome are transcribed into mRNA at different frequencies and that mRNA is either the direct product of the transcription event or is derived from precursors which need not be much larger than the mature mRNA itself. This scheme places control of gene expression firmly at the level of transcription, implies that there are control elements before each gene, and relegates post-transcriptional modification to a subsidiary role. The second hypothesis on the other hand suggests that mRNAs are derived from extremely long precursor molecules (identified with heterogeneous nuclear RNA) by a complex set of post-transcriptional steps involving specific endonucleolytic cleavage and modification of the 3′ and 5′ ends of the RNA by addition of poly(A) and methylated bases. This pathway, in which less emphasis is placed on transcriptional control, is attractive because it provides a plausible reason for the existence of mRNA.

To test these ideas, several groups of workers have studied gene regulation in animal viruses as a model system which might be expected to reflect the processes that occur in eukaryotic cells. Recent findings from one of these groups indicate that both mechanisms of control may be active.

Most of the data have been obtained with adenovirus 2, a human virus which grows well in cultured cells. Its genome consists of a linear complex of DNA about 35,000 base pairs in length, sufficient to code for 30–40 polypeptides of average size. The expression of these polypeptides is under temporal control: some of them (confusingly called early proteins) are synthesised at all times during lytic infection; others (late proteins) are sythesised only at late times. The early genes are collected into four widely-spaced regions and during the early stage of infection the only virus-specific mRNA present in the cell is complementary to one strand of the DNA sequences of these four regions (for a review see Flint *Cell* **10**, 153; 1977).

At the Cold Spring Harbor symposium, J. E. Darnell (Rockefeller University) presented evidence to show that each of these four groups of early genes has at least one promoter sequence. Nuclei were isolated from cells early during lytic infection and incubated in the presence of radioactive precursors of RNA in conditions which do not allow the initiation of new RNA chains, but merely the extension by a hundred or so nucleotides of those already begun in the intact cell. At the end of the brief incubation period the RNA was extracted and divided into different size classes by sedimentation through sucrose gradients. The shortest RNA molecules to be labelled *in vitro* should be those that had just begun to be synthesised *in vivo*. By hybridising the short RNA chains to different segments of the viral genome, obtained by cleavage of adenovirus 2 DNA with restriction endonucleases it was a straightforward task to identify the sites at which RNA synthesis had begun. Darnell and his coworkers (R. Evans, N. Frazer, S. Goldberg, T. Weber and N. Wilson) found four starting points for early RNA—two on the *r* strand at positions 1.8 and 80 and two on the *l* strand at positions 98 and 72. Because they lie at the beginning of the genes which code for early proteins it seems likely that these four regions serve as classical promoters—sequences which direct RNA polymerase to begin synthesis of an RNA chain. When infection is stringently blocked in the early phase, no viral RNA sequences are detectable in the nucleus other than those copied from the early regions. Thus expression of early viral genes seems quite clearly to be under transcriptional control.

At late times after infection a very different situation obtains. After viral DNA synthesis begins there is a vast increase in the rate of viral RNA synthesis as well as changes in the pattern of transcription. The cytoplasm contains a variety of new RNA species 1,000–4,000 bases long, that together account for virtually all the information of the viral genome. In addition the nucleus contains high molecular weight, virus-specific RNA molecules, some of which seem to be more than 20,000 bases long. More than 80% of both nuclear and cytoplasic transcripts are complementary to one strand of

---

Joe Sambrook is Senior Investigator at the Cold Spring Harbor Laboratory, New York.

viral DNA—the *r* strand. In two kinds of experiment described in the April issue of *Cell,* Darnell and his coworkers (Weber, Jelinek & Darnell *Cell* **10,** 611; 1977; Goldberg, Weber & Darnell *Cell* **10,** 617; 1977) have shown that the synthesis of the vast majority of the giant nuclear viral RNA molecules is initiated at a specific site on the adenovirus genome. Once again nuclei were isolated, this time from cells in the late stages of infection, and RNA chains were extended by the addition *in vitro* of a few hundred labelled nucleotides. The radioactive label incorporated into the longest RNA molecules was found to hybridise only to the right hand end of the viral genome: the shortest molecules, however, hybridised preferentially to a region mapping between positions 14.5 and 19.0 on the viral genome. Thus late viral RNA complementary to the *r* strand is synthesised from one long transcription unit, with a promoter near position 14.5 and a terminator near the right hand end of the viral DNA. This conclusion is confirmed by experiments in which infected cells were exposed to ultraviolet irradiation —a treatment which causes lesions in DNA through which RNA polymerase cannot pass.

The frequency at which a particular sequence of DNA will be transcribed will therefore depend on whether a lesion is introduced between the sequence in question and its promoter. If the lesions are randomly distributed throughout the population of viral DNA molecules, transcription should decrease exponentially with distance from the promoter. Late adenoviral RNA synthesised immediately after irradiation was found to hybridise most efficiently with sequences from the left hand 30% of the viral genome and progressively less well with sequences to the right. The results indicate that a late promoter is present near the left hand end of the *r* strand of adenoviral DNA.

Taken together, both types of experiment show, first, that late in adenoviral infection, transcriptional control still occurs, and second, that the site at which RNA synthesis begins is quite specific and efficient. By contrast to the early promoters however, the late promoter near 14.5 on the *r* strand is highly polar and controls the expression of all genes to its right. The primary product of transcription is a long RNA molecule complementary to DNA sequences between 14.5 and 100, which is cleaved endonucleolytically to yield mature mRNA. The shift from the early to the late phase of adenovirus transcription must therefore involve alterations not only in the genes that are expressed but also in the method by which their expression is controlled.

Mass of Saturn's rings

from David W. Hughes

MASS is one of the more awkward quantities to measure in an astronomical context. Usually it is derived from a careful analysis of the perturbing effect the gravitational field of one body has on the orbit of another or, less satisfactorily, by simply multiplying the volume of the object by an estimate of its density. Inevitably the problems and uncertainties increase as the body becomes smaller or more tenuous, so W. I. McLaughlin and T. D. Talbot from the Jet Propulsion Laboratory, California are to be congratulated on obtaining the reasonably precise value of $(3.5\pm1.4)\times10^{24}$ g for the mass of the rings of Saturn. Their calculations have been published in a recent edition of the *Monthly Notices of the Royal Astronomical Society* (**179,** 619; 1977).

The gravitational potential around Saturn is a function of the planet's mass, size and principal moments of inertia and also of the mass, size and orbits of the rings and the satellites. A knowledge of the rate of precession of the satellite orbits enables this potential to be estimated with considerable accuracy. Reliable observations of the six inner satellites, Mimas, Enceladus, Tethys, Dione, Rhea and Titan going back as far as 1888 have been analysed by Kozai (*Annls Tokyo astr. Obs. Ser.* 2. **5,** 72: 1957) and Garcia (*Astr. J.* **77,** 684; 1972) to give the precession rates of the line joining the ascending and descending nodes and also the line joining the apsides.

Using these and also values for the masses and semi-major axes of the satellites, McLaughlin and Talbot have solved the gravitational potential energy function to give values for Saturn's J_2 and J_4 (coefficients in the power expansion of the potential energy function, J_2 being directly related to the moments of inertia about the spin axis and an axis in the equatorial plane) and for the mass of the rings and of the satellite, Rhea. The first solution they presented however did not use a model for the mass distribution inside Saturn and had only a limited usefulness as far as calculating J_4 and the ring mass goes, given the latter imprecisely as $(5\pm33)\times10^{24}$ g.

A much more meaningful solution was obtained by incorporating the results of Hubbard, Slattery and De Vito's high precision modelling of the interior of Saturn (see *Astrophys. J.* **199,** 504; 1975) which led to a direct functional relationship between J_2 and J_4. The inclusion of this gives a ring mass of $(3.5\pm1.4)\times10^{24}$ g, a mass for Rhea of $(2.7\pm0.5)\times10^{24}$ g and values of $(1.664\pm0.001)\times10^{-2}$ and $-(8.7\pm0.1)\times10^{-4}$ for J_2 and J_4. The mass obtained for the rings is very close to the value obtained by Franklin, Colombo and Cook (*Icarus* **15,** 80; 1971) who used a completely different calculation based on the observations of the location of the Cassini division which occurs between the A and B ring. They found a 1,400 km discrepancy between the observed position and that predicted by assuming that the division was due to particles orbiting at that distance being in resonance with the orbit of Mimas, and thus being quickly removed by gravitational perturbation. They concluded that the shift was caused by the self gravitation of ring B thus leading to an augmentation of its outer boarder. To cause the observed shift they calculated that the rings had to have a mass not less than 3.4×10^{24} g a value which agrees surprisingly well with the McLaughlin and Talbot values of $(3.5\pm1.4)\times10^{24}$ g.

So in a mass league of planetary companions the rings of Saturn come in ninth, behind Ganymede, Triton, Titan, Callisto, Moon, Io, Europa and Titania. Also if all the mass in the rings were put together into one satellite with a density say like that of Dione and Rhea (~2.4 g cm^{-3}) this satellite would have a radius of around 700 km.

David W. Hughes is a lecturer in the Department of Physics at the University of Sheffield.

Following the leader

How mRNAs are cleaved from their nuclear precursors is totally unknown, but bizarre processes must be involved. The audience at the symposium was amazed, fascinated and not a little bewildered to learn that late adenovirus mRNAs are mosaic molecules consisting of sequences complementary to several non-contiguous segments of the viral genome. In every case so far examined, late adenovirus mRNAs contain at their 5′ ends about 150 nucleotides which are transcribed not from DNA sequences immediately adjacent to the structural gene, but from sequences which map at distant locations in the viral genome.

P. A. Sharp (Massachusetts Institute of Technology) and his colleagues, S. N. Berget, A. J. Berk and T. Harrison, described experiments in which purified mRNA coding for the major coat protein, hexon, was annealed to a restriction fragment (*Hin*dIII A) of adenoviral DNA which spans the hexon gene. When the resulting hybrids were examined by electron microscopy, only

15% were found to consist of perfect duplex structures. Protruding from the vast majority was a tail of RNA which was shown by its location and length to consist of about 150 nucleotides at the 5′ (or leading) end of the mRNA. All attempts to remove the leader sequence by incubating hexon mRNA in conditions which destroy RNA–RNA hybrids were unsuccessful, and Sharp and his colleagues were forced to conclude that the leader sequences are not complementary to DNA sequences which lie immediately upstream from the hexon structural gene. The full complexity of the situation was not apparent until hexon mRNA was hybridised to the isolated *r* strand of *Eco*RI fragment A DNA (see Fig. 1). Consistently observed were hybrids whose structure could be interpreted only as shown in Fig. 2*a*.

These results mean that mature hexon mRNA consists of four separate blocks of sequences. Measurement of the lengths of single-stranded DNA and DNA–RNA hybrids show that closest to the 5′ end of hexon mRNA is a small number of nucleotides complementary to position 16.8 on the *r* strand of the viral DNA: next come approximately 80 nucleotides coded by position 19.8; then 110 nucleotides from position 26.9 and finally the coding sequences of the hexon gene itself which maps between positions 51.7 and 61.2. The structure of the hexon mRNA is shown in Fig. 2*b*.

An identical conclusion was reached independently and simultaneously by a number of groups working at Cold Spring Harbor itself, using several different late adenoviral messengers and a variety of different assay systems. Their results may be summarised as follows:

- many if not all adenoviral late mRNAs contain an identical capped oligonucleotide (7Me Gppp ACU $[C_4U_3]$ Grp) at their 5′ end (R. E. Gelinas, R. J. Roberts)
- these capped structures are not complementary to viral DNA sequences near the major late structural genes but hybridise with DNA sequences which map between positions 14.7 and 21 (D. S. Klessig)
- many late adenoviral mRNAs which function in a cell-free system, hybridise not only to the appropriate structural gene, but also to DNA sequences which map between 16 and 32 (J. Lewis, A. Dunn, J. Hassell)
- mRNAs for fibre, 100 K, hexon and penton each contain sequences at their 5′ ends which can be seen by electron microscopy to hybridise to positions 16.7, 19.7 and 26.7 on the *r* strand of the adenoviral genome (L. T. Chow, Gelinas, T. R. Broker & Roberts).

These unexpected findings raise a number of interesting questions. How are the mosaic molecules synthesised? Why are the three leader sequences separated from each other and from the structural genes? Do the leader sequences serve any function? How general is the phenomenon?

At the symposium four possible ways were discussed by which mosaic late adenoviral mRNA might be synthesised: first, the polymerase responsible for late adenoviral transcription might jump from one segment of the viral genome to another in an ordered fashion. Second, there might be new DNA templates generated, perhaps by recombination, that would contain the appropriate arrangements of different segments of the viral genome. Third, each of the segments may be transcribed independently and the mature mRNAs may be synthesised by ligation of components. Fourth, all late mRNAs that contain an identical leader sequence may be derived by cleavage from the same nuclear precursor.

The first three hypotheses are inconsistent with the data of Darnell's group discussed above. The fourth hypothesis, however, is identical to the conclusions drawn by Darnell and his coworkers. All the mRNAs that have been shown so far to share the same leader sequence also belong to the same transcription unit and fall under the control of the promoter located on the *r* strand of viral DNA near position 14.5. By contrast a small late mRNA coded by sequences mapping between positions 9.7 and 11.1 on adenovirus 2 DNA and whose synthesis cannot be controlled by the promoter at position 14.5, contains a leader sequence which hybridises to DNA between positions 5.0 and 6.4 (Chow, Broker, Roberts & Westphal).

The best mechanism to explain these findings seems to be that espoused by Klessig. He believes that there may occur in the primary transcript, base-

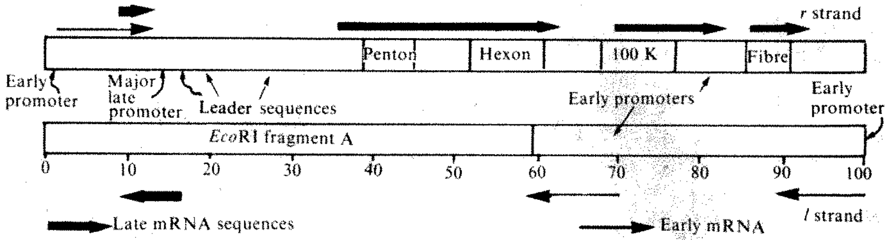

Fig. 1 Transcription map of adenovirus 2 (see Flint *Cell* **10,** 153; 1977).

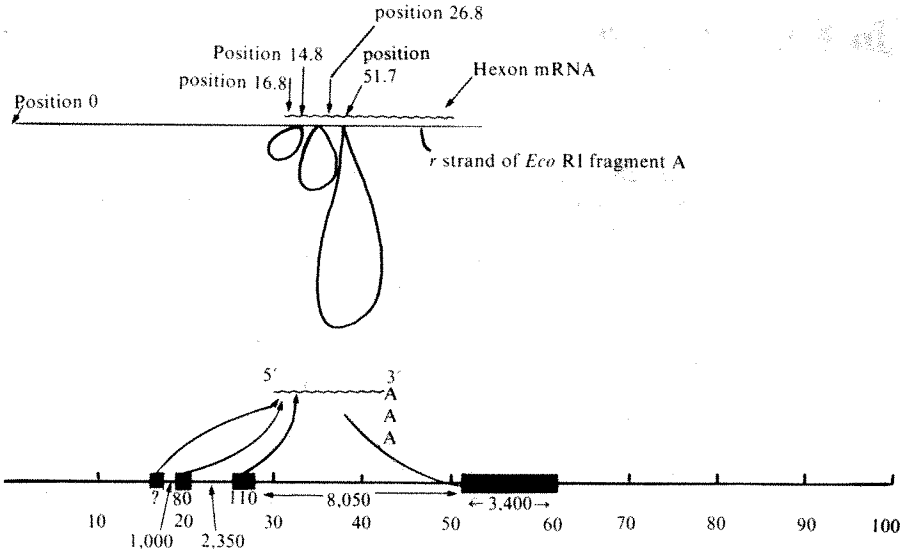

Fig. 2 *a*, Pattern of hybridisation between hexon mRNA and the *r* strand of *Eco*RI fragment A of adenovirus 2 DNA. *b*, Regions of adenovirus genome which contribute to hexon mRNA. Figures other than adenovirus DNA markers represent distances in nucleotide base pairs.

pairing between the leader sequences and the coding sequences so that mature mRNA would be derived by recombination-like events. Each precursor would then generate one mature mRNA. Perhaps separation of the several leader sequences and those of the structural genes allows several different modes of base pairing whose relative frequencies may determine the rates at which different mRNAs are produced.

The major problem is to find out how widespread the phenomenon is. Already there is evidence presented at Cold Spring Harbor by S. Weissman, Y. Aloni, G. Khoury and Ming Ta-Hsu that a similar situation may occur during synthesis of late SV40 mRNAs. But the key question is whether analogous events happen in uninfected cells. Perhaps it is not too optimistic to hope that what has been so clearly shown for adenovirus 2 may also help to explain how host cells regulate their own genes. □

Genes, channels and membrane currents in *Paramecium*

from Roger Eckert

THE ciliated slipper animalcule first observed by Anton van Leeuwenhoek in 1674, and familiar to generations of introductory biology classes and students of cytoplasmic inheritance, has lately proved increasingly useful for novel interdisciplinary approaches to problems of broad neurobiological interest. This is not a completely new departure, however, for the very first intracellular electrical measurements from animal cells were made on *Paramecium* over 43 years ago by T. Kamada (*J. exp. Biol.* **11**, 94; 1934), a pioneer in the use of saline-filled capillary microelectrodes. More recently the surface membrane of this unicellular organism was found to exhibit properties of electrical excitability (see review in *Calcium in Biological Systems* ed. Duncan, C. J. page 233 Cambridge University Press, 1976), similar in essence to those shown by metazoan nerve and muscle preparations. Most prominent is a graded depolarisation produced by an inward regenerative current in response to depolarising stimuli. The entry of Ca ions carrying this current produces a transient rise in intracellular [Ca] that mediates a reorganisation of axonemal activity seen as reversed ciliary beating with backward swimming. The stimulus–response coupling sequence is summarised in Fig. 1.

As in the classical excitable membranes of nerve and muscle, depolarisation leads to an inward current (carried in *Paramecium* by Ca) followed by a more slowly developing outward K current. The electrically excitable membrane channels that carry the Ca current seem to reside almost exclusively in the portions of the surface membrane covering the cilia, for removal of the cilia eliminates the inward Ca current, which is restored gradually as this portion of the membrane regenerates with ciliary regrowth over a period of several hours (Dunlap & Eckert *J. Cell Biol.* **70**, 245a; 1977). Interest in Ca channels is heightened by reports of their occurrence and functioning in sensory, nervous, secretory, embryonic and motor tissues, and by growing evidence that Ca entering cells often acts as a second messenger in modulating certain metabolic activities as well as membrane conductances (Baker in *Calcium Movement in Excitable Cells*, Pergamon Press, Oxford, page 7; 1975; also various articles in *Calcium in Biological Systems op. cit.* Cambridge University Press, 1976).

Paramecium offers a unique combination of features useful for new approaches to the study of the Ca system and other components of excitable membranes. As a microorganism it can be mass cultured, cloned and manipulated and analysed genetically. It also possesses the fundamental electrical properties of an excitable cell. Because Ca channels are localised in the membrane covering the cilia a greatly enriched channel fraction can be produced by collecting the cilia which have a high surface area/volume ratio. Regrowth of the cilia provides a model system for studies of channel regeneration and insertion into the membrane. In addition, the coupling between membrane function and ciliary activity facilitates identification and isolation of membrane mutants by their sensory and locomotor behavioural phenotypes. The sensitivity of the ciliary apparatus to intraciliary [Ca] also provides an independent assay of Ca entry through the channels of the ciliary membrane (see below).

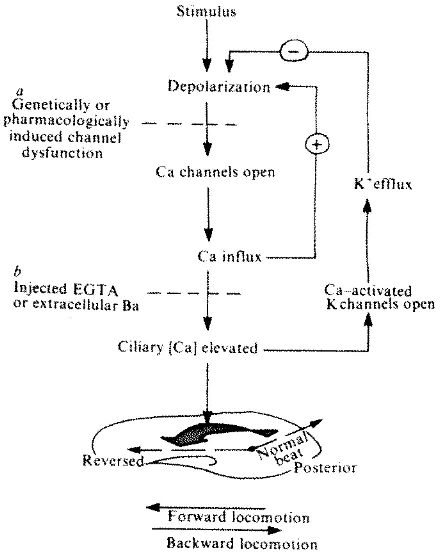

Fig. 1 Relations between channels, currents, and locomotor activity in *Paramecium*. The simulus-response coupling sequence, which proceeds from top to bottom, can be interrupted (dashed lines) in various ways; for example, by blocking the Ca channels (*a*) or by interference with intraciliary accumulation of free Ca^{2+} (*b*). Barium ions, like Ca^{2+}, promote ciliary reversal, so they do not prevent reversed swimming, although their substitution for intraciliary Ca does interfere with activation of the Ca-dependent K channels, causing Ba to promote long-lasting all-or-none action potentials with accompanying ciliary reversal in place of the brief, graded Ca response normally produced by the membrane. EGTA injection, by limiting Ca concentration buildup, interferes with both ciliary reversal and activation of the Ca-dependent K channels. This can produce prolonged all-or-none action potentials without ciliary reversal. A report in this issue (Oertel *et al. op. cit.*) demonstrates the utility of a membrane mutant in which a genetically determined Ca channel dysfunction (*a*) is used to analyse the normal behaviour of the membrane.

This issue of *Nature* contains an excellent example of the clever genetically-assisted analyses of membrane function that are being carried out on *Paramecium tetraurelia* by Ching Kung and his associates at the University of Wisconsin (Oertel *et al.* page 120). Membrane currents in response to step depolarisations of the wild type were compared with those of *pawn*, a class of mutant in which the Ca channels had been shown previously to be functionally defective. Predictably, the *pawn* membrane produced only the delayed outward K current, whereas the wild type produced, in addition, the previously reported early inward current carried through Ca channels. Averaged *pawn* current trajectories

were graphically subtracted from averaged wild-type trajectories in order to produce a difference trajectory representing the currents that are missing in the mutant. This approach is similar in concept to isolation of partial currents with the aid of ionic or pharmacological blocking agents (Fig. 1, point *a*), which, regrettably, have not worked well to date on *Paramecium*. From these analytical procedures, Oertel *et al.* concluded that the Ca current completely and rapidly inactivates within milliseconds rather than persisting under prolonged depolarisation, and that a prolonged Ca-activated K current, which might conceal the Ca current, is also absent in the wild-type membrane.

This work is noteworthy not only because it introduces a unique and interesting genetically-assisted approach to membrane current isolation, but also because it has led to important conclusions that seem to disagree with conclusions arrived at through less elegant but perhaps equally reliable means (Fig. 1, point *b*). Thus in simple membrane voltage recordings, injection into *Paramecium* of the Ca-chelator EGTA, or extracellular addition of barium ions converts the normally brief, graded Ca response to an all-or-none action potential exhibiting prolonged plateaux due to delayed repolarisation. In molluscan neurones such behavior is ascribed to diminished activation of a Ca-activiated outward K current (Meech *Comp. Biochem. physiol.* **48A**, 387; **48A**, 397; 1974), and concomitant exposure of a persistent inward Ca current that normally is short-circuited by and can be obscured by the Ca-activated K current (Eckert & Lux *J. Physiol.* **254**, 129; 1976).

The cilia, which are sensitive to the intraciliary Ca concentration, beat steadily in reverse throughout voltage clamp depolarisations for periods lasting from tens to tens of thousands of milliseconds, but revert quickly to nonreversed beating characteristic of the low resting intraciliary [Ca] on repolarisation (Machemer & Eckert *J. comp. Physiol.* **104**, 247; 1975). This precise temporal coupling of Ca-dependent, reversed beating to membrane depolarisation in *Paramecium* suggests that a Ca current continues to flow during depolarisation, maintaining an elevated intraciliary Ca concentration. Such a Ca current can easily be overlooked in current measurements if short circuited by a Ca-activated K current (see for example Clusin & Bennett, *J. gen. Physiol* **69**, 145; 1977). Rapid shut down of Ca channels (Eckert *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 1748; 1977) could make it difficult to measure the end-of-pulse tails of a persistent current. Other factors that might contribute to apparent or real Ca inactivation are: (1) the negative-going shift in the Ca equilibrium potential with attending drop in EMF driving the Ca current that occurs as the Ca activity within the restricted space of the cilia rises during Ca entry; and (2) a possible depression of the conductance of the Ca channel due to accumulation of Ca within the channel or at sites on the cytoplasmic side of the membrane. Such self-limiting behaviour may be absent with injected EGTA or with extracellular barium.

These and similar problems in sorting out partial currents are not limited to *Paramecium*, of course, so it will be of general interest to see how they are resolved. In any event, the report by Oertel *et al.* reminds us again that genetically assisted approaches to neurobiology, first applied to metazoan material by Benzer, Pak, Nirenberg, Nelson, Brenner and their associates, are not restricted to multicellular animals that possess a nervous system. It seems likely, in fact, that combined genetic, electrophysiological and biochemical approaches facilitated by the unique and fortuitous combination of properties exhibited by *Paramecium* and its relatives will contribute significantly to our understanding of excitable membranes. □

NMR of macromolecules

from Paul Calvert

The Euchem Conference on The Study of Macromolecules by NMR was held at Grasmere on 17-21 May, 1977.

NMR is no longer of wide interest as an effect in its own right but only in so far as it can yield useful chemical information. While the Euchem Conference provided no fireworks it did give a good general view of what NMR can now say about macromolecules and what can be expected in the near future. The usefulness of NMR to the study of macromolecules has increased in recent years with the development of commercial pulsed Fourier transform instruments and high field superconducting magnet spectrometers. High field (> 6.3 T) spectrometers are required to produce well-resolved spectra of high molecular weight polymers because their relatively slow motion in solution allows proton–proton interactions to broaden the lines. (1 Tesla = 10^4 Gauss. The larmor frequency of protons is 100 MHz at 2.4 T.)

Synthetic polymers

The meeting was divided into synthetic polymers, molecular motion, and biological polymers, but in essence the subject has two branches: first, the effects of chemical modification on peaks obtained from resolved spectra, and second, determination of the side group and main chain motions from the peak relaxation times. H. J. Cantow (University of Freiburg) introduced synthetic polymer structure studies, pointing out that there were now more than 100 papers describing primary structure determination in polymers by ^{13}C NMR. ^{13}C chemical shifts of aliphatic hydrocarbons cover a wide range and are additive, which has made this the standard technique for structural characterisation of vinyl polymers and copolymers; especially in industrial laboratories for the study of the effects of polymerisation conditions on structure. For instance, in ethylene–propylene copolymers it is possible to determine the lengths of $-(CH_2)-$ runs based on additivity rules and comparisons with model compounds. The chemical shifts contain information on primary structure, configuration and conformation. Thus in a polymer such as polypropylene it is possible with ^{13}C NMR to get detailed tacticity information if conformational effects can be ignored. The snag is that configurational effects only arise because different configurations adopt different conformations in solution. Hence different solvents can give very different shift patterns and small compound model data can be misleading. The structure of the poly(diene) rubbers is more complicated with 1,4 and 1,2, *cis* and *trans*, and head–head, head–tail and tail–tail structures, so that the peak assignments are still not sorted out. Papers by K. J. Ivin (University of Belfast) on polycyclopentenes and polynorbornenes, and by F. Schue (Montpellier) and Y. Shabab (University of Surrey) on polypentadienes dealt with these aspects. Conformational effects are of great interest from the point of view of the solution and melt properties of polymers, but are in a primitive state. Cantow described attempts of his group to relate the observed temperature dependence of chemical shift to conformational energy diagrams.

While it is very nice to have detailed tacticity information, it would be good to see it put to use to further our understanding of polymerisation or polymer properties. A. Zambelli (University of Milan) showed how this can be done in experiments where, by looking at 'mistakes' in isotactic and syndiotactic polypropylenes, he was able to show that isotactic polymerisation is directed by the

---

Paul Calvert is a lecturer in Polymer Science at the University of Sussex.

catalyst whereas in syndiotactic polymerisation it is the polymer chain which governs the orientation of a newly added unit. On occasions the results presented at the conference appeared to be a sophisticated catalogue, whereas experiments such as this present more meaty concepts.

Two papers dealt with thermosetting resins, the cinderellas of polymer science, J. R. Ebdon (University of Lancaster) on ureaformaldehyde resins and H. Pyszora (BP, Sunbury-on-Thames) on phenol–formaldehyde resins. Here NMR can only yield information about the early stages of reaction as cross linking causes loss of resolution as the molecular mobility decreases. The main lesson is that ^{13}C NMR is very useful if, as in many vinyl polymers, the tedious process of assigning peaks has already been done.

Biological polymers

Much effort in synthetic polymers is given to picking out rare events such as branches and chain ends. In proteins every group is a rare event, and the problem is first to get a resolved spectrum at all and then to get enough information to tell which peak is which. A. Allerhand (Bloomington University), Indiana showed how the non-protonated carbons of aromatic amino acids in proteins could be identified by ^{13}C NMR. These have the advantage of giving sharp peaks since they are not relaxed by attached protons, and they are spread over a wide range of chemical shift. Peaks are assigned by *p*H titration and chemical modification including use of bound lanthanide shift reagents. He described studies of tyrosines in myoglobins and histidines and tyrosines in lysozyme. The peaks get broader for larger proteins and high field instruments (> 4 T) will not improve resolution for the non-protonated carbons as chemical shift anisotropy dominates the relaxation. K. Wuthrich (STH, Zurich) showed how high field (8.4 T) proton NMR can be used to get well-resolved spectra of proteins of up to 20,000 daltons with digital resolution enhancement methods. Peaks were identified by titration, double resonance and by two dimensional Fourier transformation against chemical shift and J-coupling, to allow multiplets to be picked out. I. D. Campbell (University of Oxford) described similar experiments devised in Oxford. He showed how presaturation pulses can be used to invert and so identify multiplets and to measure exchange rates for labile protons.

These methods are most informative for proteins whose primary and X-ray structures are already known, so that amino acids can be definitely identified. Under these circumstances it is possible to study the effects of *p*H and ligands on structure and pick out hydrogen-bonded groups by deuterium exchange. In denatured proteins chemical shifts for identical residues become equal so the chemical shifts in the spectrum of a native protein must contain a great deal of conformational information which cannot be interpreted as yet. A number of papers described the interaction of ligands with proteins. J. Feeney (National Institute for Medical Research, London) discussed the binding of antifolate drugs and drug fragments to dihydrofolate reductase. The effect on histidines could be observed by *p*H titration, and on tyrosines and tryptophans by ^{19}F and ^{1}H NMR of enzymes produced by bacteria fed with fluorinated and deuterated amino acids. Binding of the NADPH cofactor could be followed by ^{31}P NMR, showing a conformational change in the pyrophosphate group and that the 2′-phosphate group binds as a dianion. In a similar vein B. Lindman (Lund University) described studies of halide binding to proteins using chlorine, bromine, and iodine NMR (see Lindman & Forsen in *Nmr Basic Principles and Progress* **12,** Springer Verlag, Berlin): it was possible to determine the stoichiometry of binding and, in the case of metalloenzymes, whether or not the halide binds to the metal. W. E. Hull, (Bruker, West Germany) described ^{19}F NMR of alkaline phosphatase to follow metal ion binding and ^{31}P to follow phosphate interactions. Weill described studies of cobalt and manganese in binding to polyelectrolytes by following the relaxation behaviour of the water. The overall message here seems to be that binding studies can be very informative if the NMR technique and ligand are well matched, and several independent measurements can be made. Otherwise there is often a large element of uncertainty as to interpretation.

Molecular motions

Since the advent of pulse Fourier transform spectrometers T_1 relaxation time measurements have become simple to carry out, and molecular motion studies have become an integral part of most macromolecule experiments. F. Heatley (University of Manchester) described studies of synthetic polymers in solution by ^{13}C and high field proton NMR. Measurements of correlation times from T_1 values and nuclear Overhauser enhancements disagree with one another to the extent that a correlation time distribution rather than a single time must be adopted. From proton relaxation times it is possible to show that a χ^2 correlation time distribution cannot fit the data over a wide temperature range, but that a molecular jump model can be used in combination with overall molecular rotation. These models seem to have great potential and are based on an enumeration of the possible conformational changes of chain segments with fixed ends. For a diamond lattice, for instance, these jumps involve motions of three and four bonds simultaneously (see Valeur *et al. J. Polymer. Sci.* (*Physics*) **13,** 667, 675; 1975).

N. Gronski (Freiburg University) and H. C. Broecher (University of Hamburg) used such models for polydienes and polyisobutylene, and F. Laupretre (Paris) for polystyrene. One criticism of this work is that there is little effort to compare the results with those from dielectric and other relaxation methods. On the biopolymer front T_1 values are extensively used to measure exchange processes and to look at phenyl group rotations, though in this latter case, it is hard to distinguish between full rotation and oscillations (see *News and Views* **258,** 112; 1975). This is an area where we can expect a lot of progress and consequently an increase in our knowledge of conformational flexibility of proteins in solution. High resolution NMR of solid polymers using a combination of high power proton decoupling and magic angle spinning was described by J. Schaeffer (Monsanto, St Louis) who related the correlation time data to the mechanical properties of the polymers (see *News and Views* (1976) **261,** 457; 1976 and *Macromolecules* **10,** 384; 1977).

NMR of polymers has often been accused of never generating indisputable information. This is becoming less true, particularly if the applications are carefully chosen. The advantage of NMR over other techniques is that resonances from individual groups are observed and can be monitored to give detailed information about their states (motional, configurational, conformational, ionisation). A disadvantage is the limited frequency range available which often can make the results ambiguous. For enzyme studies a further disadvantage is that even for ^{1}H NMR relatively large amounts of sample (0.5 ml of 0.5 mM solution) are required. ☐

Neoplastic transformation

from N. A. Mitchison

The Dahlem Conference on Neoplastic Transformation was held in Berlin on 9–13 May, 1977, and was organised by Dr Silke Bernhard. The proceedings will be obtainable from Dahlem Konferenzen, Delbrückstrasse 4c, D-1000 Berlin 33.

THE conference aimed at assessing current knowledge and tried to pose questions that would draw attention to gaps in our understanding of the process by which normal cells become tumours. One was left with the vivid impression that cancer research continues to provide an area of excitement, in which much of what is new in biology comes up for scrutiny An account of the proceedings will be published within six month. The participants mentioned in this report are not necessarily, of course, the authors of the views which they discuss.

Epidemiology was much discussed. Interest is at present greatest in environmental causes of cancer, having moved from previous concern with radiation and viruses. The strongest view (Muir) is that as much as 80% of cancer may be caused by environmental agents. The evidence comes partly from direct study of the effects of tobacco and alcohol, which are known to cause about 40% of cancers in Western males, and partly from study of particular industrial hazards, known to cause at least 1%. Comparisons between different environments tend to support the environmentalist view; the difference in cancer incidence between Mormons and their fellow US citizens, for example, is especially striking (C. S. Muir, International Agency for Research on Cancer, Lyons: R. W. Miller, National Cancer Institute, Berthesda). On the other hand it can be argued that all cancers are 100% genetic, just as they are also 100% environmental in origin. And although early pregnancy protects statistically against cancer of the breast, J. Cairns (Imperial Cancer Research Fund, London) pointed out that one cannot usefully describe the avoiding of pregnancy as an environmental cause of cancer.

Widespread use of the Ames test has confirmed the mutational origin of cancer (A. G. Knudson, Institute for Cancer Research, Philadelphia). The monoclonal nature of most tumours supports this view (P. J. Fialkow, Veterans Administration Hospital, Seattle); the exceptions to this rule are understandable, for example, hereditary multiple neurofibroma or infective warts. So also does the predisposition to cancer in inherited defects in DNA repair, particularly xeroderma pigmentosum and ataxia telangectasis. Somatic genetics has now reached the point where the first of these diseases can be subdivided into six complementation groups, and the second into three. Yet further support for the mutation view comes from the biochemistry of DNA repair: the failure to excise O^6-ethylguanine explains why ethyl nitrosourea causes tumours in the rat brain (K. Rajewsky, Universität Köln). We are left with two main questions: how important are endogenous carcinogens; those detected by mutational screening of bile or urine (P. N. Magee, Temple University, Philadelphia) for example, and do environmental carcinogens act as promoters rather than as initiators (Cairns)?

How do viruses transform cells (W. Doerfler, Universität Köln; E. L. Winnaker, Universitat Munchen; C. M. Croce, Wistar Institute, Philadelphia)? The nearest we can come to answering this question at present is to find out whether SV40 or the RNA leukaemia viruses integrate into a definite site in the host genome, presumably adjacent to the oncogene(s). The evidence is still inconclusive. Cutting the genome of SV40-transformed cells with restriction enzymes suggests that integration is promiscuous; but cell hybridisation studies indicate that integration occurs preferentially in human chromosomes 7 or 17 (Croce). Further analysis using restriction enzymes should answer the question.

A respectable case can be made for the proposition that cancer results not from a stable genetic change, but from a reversible form of differentiation. Thus, in chimaeric mice, genetic markers from teratomas have been detected in normal, differentiated tissue (R. L. Gardner, University of Oxford); however, the most dramatic finding, by B. Minz, that teratoma-derived gametes can give rise to normal offspring, has yet to be confirmed. Since at least nine different chemical factors control the growth of cells in vitro (C. H. Sato, University of California, San Diego)—and the list is rapidly growing—there is plenty of scope for control of differentiation. However, the decisive experiments have proved curiously elusive: nuclear transplantation, or the isolation of normal cells from tumours other than teratomas.

Cancer immunology survives, in spite of the collapse of immunological surveillance as a general theory. Indeed, surveillance probably does operate, but only in restricted circumstances involving viral antigens such as nasopharyngeal carcinoma of the Chinese. Up to date cellular immunology links up with cancer when the question is posed whether manipulation of the immune system may reveal otherwise undetectable responses to weak tumour antigens (B. A. Askonas, National Institute for Medical Research, London; Rajewsky; K. P. Eichmann, Institute fur Immunologie und Genetik, Heidelberg). The idiotype network, and T helper cells, provide logical handles for such manipulation. The most exciting development in cancer immunology has been the discovery that tumour specific antigens and major histocompatibility antigens interact in several ways (E. S. Lennox, MRC Laboratory of Molecular Biology, Cambridge). Thus new H-2 specificities occur on cancer cells, as a result either of derepression or post-translational modifications. This implies that the molecular biology of the tumour specific antigens may be more accessible than had been expected. ☐

N. A. Mitchison is Professor in the Department of Zoology and Director of the ICRF Tumour Immunology Unit at University College, London.

Snake's eye view of Adam and Eve

from K. W. Jones

A MOLECULAR difference at the DNA level between human males and females (surely fuel for the current debate on whether or not man is man or merely person) is the substance of recent work by Kunkel *et al.* (*Science* **191**, 1189; 1976). Males possess a Y chromosome which is absent from normal females and carries the gene(s) which determines primary sex. By reassociation of traces of male DNA with an excess of female DNA these workers have isolated a class of repeated DNA (It-Y DNA) which does not reassociate with female DNA, but which will reassociate with male DNA. It is therefore presumably of Y chromosome origin. More recently (*Proc. natn. Acad. Sci. U.S.A.* **74**, 1245; 1977) the same workers have analysed the content of It-Y DNA in the DNA from individuals with various structural abnormalities of the Y chromosome and shown that It-Y DNA comprises 15–30 different families of reiterated sequences, is largely located on the fluorescent part of the long arm of the Y and amounts to about 10% of the total chromosome. This constitutes the first characterisation of repeated DNA unique to a single human chromosome. The fact that it is on the Y chromosome immediately poses the question of its role in sex determination but, as the authors point out, such a role is rather unlikely since in their study some normal males with small non-fluorescent Y chromosomes lacked It-Y DNA whereas some females with Y translocations did possess it.

Recently Cooke (*Nature* **262**, 182; 1976) has described repeated DNA specific to human males and amounting to 50% of the Y chromosome. This was detected by digesting DNA from males and females with the restriction enzyme *Hae*III which cuts DNA at a short defined base sequence to yield fragments of different lengths defined in distribution according to the spacing of the target sequence cleaved by the enzyme. When the fragments were separated by gel electrophoresis in agarose, DNA bands were seen in the male digest which were absent from the female digest, suggesting the unique presence of a repeated sequence containing the *Hae*III target site in male and therefore in Y chromosome DNA. Since this large fraction of Y chromosome DNA is not included in the It-Y DNA recovered by Kunkel *et al.*, it must now be supposed that it is sufficiently homologous with DNA present in the female to be removed by reassociation analysis. From my own observations, Cooke's DNA fractions are located essentially in the fluorescent region of the Y along with the It-Y DNA.

Highly repeated simple sequence (satellite) DNAs in man are also concentrated in the fluorescent long arm of the Y as well as being widely represented in many other human chromosomes. The relationship of the satellite DNAs to the other Y-repeated DNAs is not known at present and their quantitative contribution to the Y DNA as a whole is also not determined. It seems however that most of the Y chromosome long arm is composed of repeated DNA and that of this, only It-Y DNA is unique to this chromosome. The implication of the finding that It-Y DNA maps to the fluorescent long arm of the Y is that the entire repeated DNA of the remainder of the chromosome, including that in the region which contains the sex-determining gene(s) is sufficiently homologous with DNA present elsewhere in the genome to be included in the fraction which reassociates with female DNA in the conditions of Kunkel *et al.*'s experiments. This is perhaps not too surprising since the X and Y chromosomes were presumably homologous at some early period in their evolution, and it has been suggested that they are derived by a process of translocation from structural homologues (see Lyon *Nature* **250,** 651; 1976).

The significance of the high concentration of repeated DNA on the Y chromosome or indeed of the significance of most non-transcribed repeated DNA is unknown. According to Miklos and Nankivell (*Chromosoma* **56,** 143; 1976) satellite DNA may play a part in controlling the frequency of crossing over between homologous chromosomes. By crossing over, pairs of chromosomes remain largely homologous through the frequent interchange of DNA. Conversely, chromosomes which fail to cross over will tend to evolve divergently. Some change inhibiting crossing over would therefore seem to be a primary requirement for the evolution of specialised sex chromosomes.

Snake's eye view

According to Singh *et al.* (*Chromosoma* **59,** 43; 1976), in the snakes, which exhibit the entire process of evolution of sex chromosomes, the first discernable change is in the repeated DNA structure of one of a pair of chromosomes bearing the sex determining gene(s). Within the snakes there is a range of forms from primitives with no defined sex chromosomes through intermediate forms with definite, though morphologically identical, sex chromosomes, (called ZW in the female, which is heterogametic, and ZZ in the male which is homogametic) to forms with highly differentiated, morphologically dissimilar Z and W chromosomes. The primitive snakes show no difference between male and female in highly repeated (satellite) DNA whereas the intermediate forms show very obvious differences involving the appearance of novel satellite DNA in the female. This novel DNA maps exclusively, by *in situ* hybridisation, to the W chromosome (which is the functional equivalent of the Y in mammals) where it is spread over the entire length. The identical-looking Z chromosome lacks this DNA. The W chromosome also shows a different cycle of DNA synthesis from the Z, as is frequently the case in other satellite-DNA-rich chromosomal regions. Singh *et al.* suggest that this interferes with pairing between the Z and W thus predisposing to their divergent evolution and accounting for the fact that in the most evolutionarily advanced group of snakes the W (like the Y in man) has become greatly reduced in size and modified in form relative to the Z. The modified W chromosome nevertheless has conserved the satellite DNA sequences found in the W of the intermediate group, as determined by molecular hybridisation, as well as its allocyclic DNA synthesis pattern. From this it may be suggested that in the human Y chromosome the plethora of simple sequence DNAs reflects the molecular end consequences of the mechanism which played a part in its specialisation. Once a chromosome, like the Y, is genetically isolated, the constraints on acquiring, or amplifying, additional non-transcribed (functionless) DNA sequences are probably lost. The Y chromosome is therefore likely to be loaded with "junk DNA" (Ohno *Hoechst Symposium;* 1972) which no longer serves a useful purpose. At a practical level, however, it now seems a feasible and exciting prospect to use the It-Y DNA as a handle to fish out covalent Y chromosome DNA sequences by some type of DNA affinity chromatography. This will shed further light on the structure and evolution of the human Y chromosome and it may ultimately permit a direct approach to the molecular basis of sex determination at the DNA level. ☐

A hundred years ago

In the debate on the education estimates, on Tuesday night, Sir John Lubbock, speaking on the extra subjects which had been made compulsory, said he doubted whether under any circumstances it would be desirable thus to stereotype one form of education for the whole of England; but surely we ought not to do so unless we were very clear as to what is the best system. There was, however, very great difference of opinion on this head. The first authority to which he would refer was that of a committee of that House. It was presided over by his hon. friend the member for Banbury, and after careful enquiry they reported that in their opinion "elementary instruction in the phenomena of nature should be given in elementary schools." The next authority which he would quote was the Royal Commission, presided over by the Duke of Devonshire, which unanimously recommended that more substantial encouragement should be given to the teaching of the rudiments of science in our elementary schools. In Scotland, too, great dissatisfaction was felt with the present system. At the last conference of elementary teachers, held in London, which was very numerously attended, it was resolved that the system of payment "embodied in the Code is unsound in principle and injurious to the progress of true education." The inspectors of schools differed greatly as to the most suitable subjects. Even in regard to geography they were not unanimous. It was said as a subject to lend itself very much to "cram." One of the inspectors gave in support some very amusing answers. For instance, in answer to a question of "What are mountains and rivers?" one girl replied "Mountains in some parts of the world are very useful. In Africa, for instance, they shoot out gold." Of rivers she had not so favourable an opinion, though she thought "they were all very well in some countries where there was very little rain." He confessed, however, that he thought geography a very good subject, though he was not convinced that it ought to be continued during the whole course to the exclusion of other subjects. The mere skeleton of history taught in our elementary schools contained little more than dates, wars, and murders; but dates and crimes no more constituted the history of a nation than sinews and bones made a man. Men of science must be grateful to Sir John Lubbock for so constantly urging upon Government the importance of scientific education.

Transposable genetic elements as agents of gene instability and chromosomal rearrangements

Patricia Nevers & Heinz Saedler*

Transposable genetic elements in prokaryotes and eukaryotes, when inserted at a given locus, can control expression of the locus and cause large scale rearrangements of adjacent DNA sequences. Striking similarities in genetic behaviour between the two groups of elements have led to the proposal of a molecular model of eukaryotic controlling elements, and to suggestions about the part such elements may play in evolution and differentiation.

CHROMOSOMES are commonly regarded as conservative structures in which an exact amount of genetic information is arranged in a definite sequential order. This order is normally preserved when information is exchanged between chromosomes, and guaranteed by a set of recombination enzymes that function only with paired sectors of homologous DNA. But processes such as inversion, deletion, duplication, and translocation, often involving recombination between apparently non-homologous chromosomal regions, can alter the sequence of genetic information. The resulting chromosomal rearrangements have been observed in some cases with a disturbingly high frequency, inviting speculation about their biological significance. The processes involved have been termed collectively 'illegitimate recombination',[1,2] reflecting the bias for conventional pathways based on sequence homology; but evidence now accumulating may legitimise them as important mediators of evolution or even differentiation.

Classical geneticists have known for decades that eukaryotic chromosomes can behave unconventionally, giving rise to unexpected changes in phenotype. In the somatic tissue of plants or fruit flies, random spots of pigment arise against a background that is otherwise colourless, resulting in a mottled or variegated appearance. Closer examination of this phenomenon in maize led Barbara McClintock to the postulation that distinct genetic units—so called 'controlling elements'—are responsible for such changes in gene expression[3]. Drastic alterations of chromosome organisation, such as deletions, inversions and duplications, were often found in association with loci containing controlling elements[4]. Moreover, a given controlling element did not remain fixed at a particular site in the chromosome, but seemed to be capable of moving from one position to another, causing instability of gene expression and structural alterations at each new locus[5–9].

Thus controlling elements were revealed as possible agents of illegitimate recombination. But, as with many discoveries in classical genetics, interest in these elements was confined to a small group of scientists until molecular biologists succeeded, fifteen years later, in isolating analogous elements, the insertion sequences (IS), in prokaryotes[10–12].

The properties of IS-elements in bacteria and controlling elements in *Zea mays* have been described in detail elsewhere[9,13]. The aim of this article is to outline briefly what is known about bacterial insertion sequences at the molecular level, concentrating on the elements IS1 and IS2; to draw attention to parallels between the elements of eukaryotes and prokaryotes; to interpret data on eukaryotic controlling elements in the form of a molecular model; and to suggest what part these elements may play in evolution or differentiation.

IS elements in bacteria

Studies on the galactose and lactose operons of *Escherichia coli* revealed an unusual group of mutants that were shown conclusively to be caused by the insertion of a segment of DNA into the operon (for review, see ref. 13). When integrated in a gene of an operon, a DNA sequence of this kind not only abolishes the function of the gene, but also leads to a reduction in the activities of all other genes downstream in the direction of transcription, an effect known for historical reasons as polarity. (The term was originally used in connection with 'polar' mutations, in which the expression of genes downstream of the mutation is inhibited. Although it is now known that it is transcription that is polar, the mutations merely interfering with its progress, they are still said to 'cause polarity')[13–17]. The insertion sequences investigated so far fall into five non-homologous classes: IS1, IS2, IS3, IS4 and IS5 (for review, see ref. 18). The small size of these elements (800–1,400 nucleotide pairs), equivalent to only one or two genes, indicates that they differ from any known bacteriophage, and indeed, they seem to represent material displaced from the bacterial chromosome rather than invaders from without[19–21]. Eight copies of IS1 and five of IS2 are found as natural residents of wild-type *E.coli* chromosomes. Examination of their properties at 'unnatural' positions in the galactose and lactose operons has been conducted in order to gain information about their possible biological significance as components of wild-type chromosomes.

Polar effects of IS-sequences

The polar effects of insertion sequences have been shown to be due to interference at the level of transcription[22]. While the physical presence of an element in an operon causes some reduction in transcriptional read-through, a maximal block

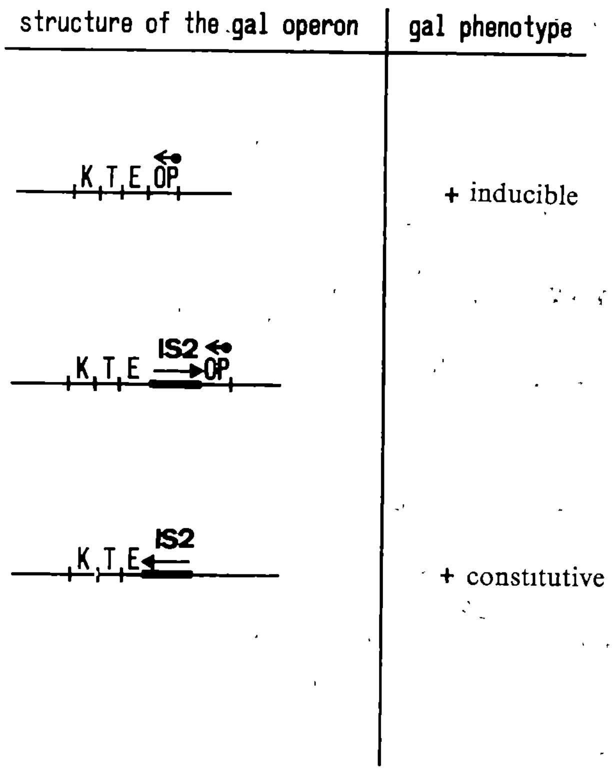

Fig. 1 Control of gene expression by IS2. Expression of the three genes of the galactose operon of *E. coli*—galactokinase (K), transferase (T), and epimerase (E)—before the insertion of IS2 is shown in line one. The genes are under normal operator/repressor control and expressed only in the presence of an appropriate inducer. Integration of IS2 into the operator region in polar orientation abolishes operon expression (line 2). Integration of IS2 in the opposite orientation leads to constitutive expression of the operon[38]. Long arrows indicate the orientation of IS2 and short arrows the direction of transcription from the operator region.

is achieved through the action of the bacterial protein rho[23-27]. According to a recent model of normal transcription termination in bacteria and phage[28], the rho protein recognises specific DNA sequences, the terminator sequences, at which it stops transcription. However, in order to be effective, rho must react with ribosome-free mRNA at these sites. This condition could be met if so-called 'nonsense' codons are situated immediately ahead of a terminator site. At these codons, for which no corresponding amino acids exist, translation ceases and ribosomes are released from the mRNA[29]. Thus it is possible that IS elements contain a combination of nonsense and terminator sequences which lead to rho dependent termination of transcription.

Excision of IS-elements

Wild-type revertants of IS-induced mutations, in which the IS-element is missing, can be found with a frequency of one in ten million[10,23]. They are thought to arise by exact excision of the IS element. Since normal function of the gene is restored, the integration and excision of the element must be possible without damage to the gene. But such precision is not always the rule, and in some cases, integration or excision is accompanied by deletions of bacterial material adjacent to the insertion site[13,30,31]. The enzymes involved in integration and excision have not yet been identified, but they are independent of known recombination enzymes, since both events occur in rec A hosts[14,32].

Transposition of bacterial DNA insertion elements

The excision of an IS sequence followed by re-integration of the element at another site is termed transposition. This process has been examined most extensively with transposons—elements closely related to IS sequences and which have been the subject of a recent review[33]. A transposon is a length of DNA embracing several genes and bordered at each end by identical sequences in reverse or direct orientation to each other. In a number of cases these termini consist of known IS sequences, while the intermittent material may include genes for resistance to antibiotics, positive markers which can be used to monitor the movements of the transposon. Transposons have thus been shown to move from the R (resistance) plasmid, in which they normally reside, to other plasmids such as the F (fertility) plasmid, to the bacterial chromosome, and to various bacteriophage DNAs as well (for review see ref. 33).

Transposition may be mediated by enzymes that are able to recognise the termini of insertion sequences and certain bacterial sequences. Alterations of these sequences, such as deletions, may influence the efficiency of transposition, as shown with the ampicillin transposon TnA (ref. 34). Transposition occurs in rec A hosts[35-37], which indicates that transposition enzymes are also independent of normal recombination functions. In one case, that of TnA, the transposon itself seems to code for transposition functions[34].

Control of gene expression by IS2

It seems that insertion sequences may be the components of a unique system of negative control, eliminating gene and operon activity on integration (see section on polar effects) and restoring it through precise excision. But from an evolutionary point of view a more interesting feature of IS elements may be their ability to implement positive control, as illustrated by the element IS2 (Fig. 1). While IS1 reduces operon expression when integrated in either direction, IS2 does so only when integrated in a particular orientation, orientation I. When it is in the opposite orientation, orientation II, genes located downstream are expressed constitutively at a level three times higher than normal[38]. This has been shown to be due to the presence on IS2 of a promoter at which transcription can be initiated[39]. This promoter may have other consequences when IS2 is integrated in orientation I, when transcription from the IS2 promotor may run head-on into an RNA polymerase coming from the existing promoter of the operon, thus contributing to the inhibitory effect of IS2 in orientation I (ref. 40).

The two antipodal effects of IS2 suggest that it can act as a simple switch. This is particularly appealing in view of evidence suggesting that 'flip-flop' control mechanisms underlie phenomena such as the alternating production of two different types of flagella in *Salmonella*[41-43] or the determination of mating type in *Schizosaccharomyces*[44]. An essential feature of such a switch mechanism would be the inversion *in situ* of IS2 or an equivalent element. There is genetic evidence for the inversion of IS2 in *E. coli*[38], although it has not yet been demonstrated by physical means. That inversion may represent a fundamental mode of regulation is shown by data from the bacteriophage mu. Inversion *in situ* of the so called 'G'-loop in this phage is clear both from genetic and from physical evidence[45,46].

IS sequences involved in chromosomal rearrangements

As striking as IS control of gene expression are the chromosomal rearrangements found in association with some insertion sequences. One prominent example is that of IS1-mediated deletion[31,47], illustrated in Fig. 6*a*. Sequences adjacent to this element are deleted with a frequency 10^2–10^3 times greater than the spontaneous frequency. In the cases investigated so far, IS1 is left behind in the chromosome during this process and continues to cause secondary deletions. IS1-mediated deletions all start at one terminus of the element and extend into the chromosome, ending at various non-random sites so that different classes of deletions occur with characteristic frequencies. Here too rec A-independent enzymes capable of recognising an IS terminus and certain chromosomal sites seem to be involved. Preliminary steps towards the identification of these enzymes have been made by the isolation of a bacterial mutant in which IS1-mediated deletion is reduced fortyfold[48]. Interestingly, the frequency of IS1 excision is not affected in the mutant, which suggests that different sets of enzymes are involved in these two processes.

Another type of rearrangement, duplication, can theoretically arise if chromosomal material is deleted in the form of a transposable structure which moves from one daughter strand to the other during replication. Duplications in association with an IS-element have been observed in mutants harbouring IS2 in the operator region of the galactose operon[49].

Controlling elements in *Zea mays*

In general, the effects of controlling elements in maize parallel those of DNA insertions in prokaryotes: integration of an element into a locus may produce a mutant phenotype, while accurate excision in some cells leads to clones in which normal expression of the locus is restored. If the locus at which an element is integrated contributes to a visible phenotype, such as pigmentation, occasional excision of the element during development results in a variegated appearance. In maize two kinds of element can be distinguished[9,50]: entities with no known gene products, referred to as receptor elements, and more complex, trans-acting units called regulatory elements. These elements can undergo integration, excision and transposition, for which specific enzymes may be postulated, as with bacterial DNA insertions. In maize, however, activities corresponding to such enzymes are supplied by the regulatory element itself, in a manner analogous to the bacterial TnA transposon (see section on transposition of DNA insertions). A regulatory element can thus move autonomously and govern the movements of receptor elements as well. The combination of a trans-active regulatory unit and a non-autonomous receptor element constitutes a two-element system, several of which have been found in maize, including the systems activator–dissociation (modulator), dotted, and Spm (enhancer).

These systems are entirely independent of each other, exhibiting no cross reactions between the regulator functions of one system and the elements of another. A detailed review of controlling elements in maize has been presented in a recent article[9].

For the following discussion we have selected Spm (suppressor–mutator), equivalent to En (enhancer) as a representative system, since it has some unusual properties not seen in other systems and has been the most thoroughly investigated. At this point it should be noted that most of the evidence for controlling elements has been obtained by classical genetic means. We shall waive a comprehensive presentation of this evidence and offer an interpretation on a molecular basis instead, in the hope of encouraging more widespread interest in this subject.

Fig. 2 States of the A1 locus in *Zea mays* and influence of Spm on gene expression. In wildtype kernels, in which no controlling element is present at the A1 locus (row 1), anthocyanin production and pigmentation are maximal and independent of the presence of Spm elsewhere in the genome. The degree of background colouration in all other kernels indicates the expression of the A1 locus as a function of Spm activity. Black spots correspond to clones in which a controlling element has been excised from the A1 locus under the influence of Spm mutator activity. The white spots on the kernel in row 9 are due to inactivation of Spm in two cells and their progeny. (For further explanation, see text).

phenotype of kernel	A_1 locus	state	Spm activity	location of Spm
	A_1		+ and −	not at A_1
	$a_1^{m}(-5)$		−	A_1
	$a_1^{m}(-5)$		+	A_1
	a_1^{m-1}	1	−	none
	a_1^{m-1}	1	+	not at A_1
	a_1^{m-1}	2	−	none
	a_1^{m-1}	2	+	not at A_1
	a_1^{m-2}	1	−	A_1
	a_1^{m-2}	1	+	A_1

Integration of an Spm element at the A_1 locus

The A_1 locus on chromosome 3 of *Zea mays* is one of a number of loci that contribute to anthocyanin production. As with most eukaryotic loci, the exact molecular nature of A_1 is unknown, but it may embrace several structural genes together with extensive control regions. Accordingly, various kinds of mutant can result, depending upon the position in the locus into which an element is inserted. For example, integration into a structural gene could lead either to total loss of the corresponding gene product or to loss of its distal end, resulting in a modified product. An element situated between a gene and its promoter may block transcription completely, allow a reduced level of expression, or have no effect at all.

In the mutants a_1^{m-5} (ref. 51) and the original a_1^m (ref. 52), the regulatory unit of the Spm system, referred to simply as Spm, is integrated in the A_1 locus. Anthocyanin production is eliminated in a_1^{m-5} and a_1^m kernels, but frequent, self-induced excision of the elements during plant growth results in pigmented sectors (Fig. 2, rows 2 and 3).

Trans-active functions of Spm

In the mutant a_1^{m-1}, as opposed to those discussed above, only the receptor element of the Spm system is incorporated in the A_1 locus[3]. In the original isolate of this mutant, expression of the A_1 locus is barely affected, and kernels exhibit a relatively high level of homogeneous pigmentation in the absence of Spm regulatory activity (Fig. 2, row 4). When an active Spm is present at some other position in the genome of a_1^{m-1} kernels, a different phenotype is produced. In these kernels, containing both elements of the Spm system, background coloration is abolished completely (Fig. 2, row 5). This reflects a unique property of the Spm regulatory element, which produces a suppressor activity that interacts with the receptor element at the A_1 locus to eliminate A_1 expression in the background tissue of the kernel. However, pigmented spots arise through excision of the receptor element from the A_1 locus under the influence of a second Spm activity, the mutator. The two trans-active Spm functions, suppressor and mutator, seem to be able to undergo mutation independently[53,54], which suggests that they are coded by separate genes on Spm.

States of a locus

In addition to mediating excision, the mutator product of Spm can induce inheritable alterations of the receptor element, leading to new 'states' of the locus in which it resides[54,55]. For example, exposure of the receptor element in a $^{m}_{1}{}^{-1}$ plants to Spm mutator activity leads to derivatives with new properties, representing different 'states' of the a_1^{m-1} locus[53,54] (see Fig. 2, rows 4–7). Some states derived from a_1^{m-1} show new levels of homogeneous pigmentation in the absence of Spm. Other states, derived from the allele, a_2^{m-1}, (ref. 56) respond to the suppressor but not the mutator activity of Spm, or vice versa. Still other, stable derivatives with a mutant phenotype respond

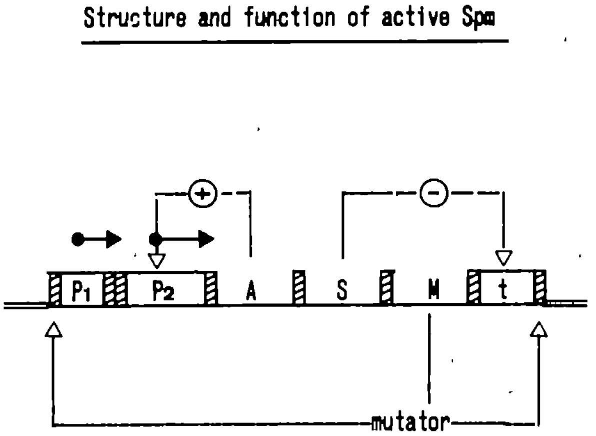

Fig. 3 Proposed structure and function of active Spm. A model of the molecular structure of an integrated Spm regulator element is illustrated. At one end of the element are two units, each with a promoter, P1 and P2. The direction of transcription from these promoters is indicated by the arrows above them. At the other end of Spm is a unit with a terminator sequence, t. Three structural genes are included in the element, coding for the A (activator), S (suppressor), and M (mutator) products. The action of these products is depicted by the dashed lines. The suppressor product operates at the t sequence to terminate transcription, as indicated by the symbol ○. The activator product, on the other hand, has a positive effect on transcription (○), by activating the P2 promoter. The mutator function of Spm is involved in excision of the element at the terminal sequences. So-called 'black box sequences', at which recombinational events such as inversion, deletions and duplications can occur, are represented by vertical hatched bars.

to neither Spm activity. One explanation is that new states arise through recombinational events such as inversions, deletions and duplications, or through conventional mutational events within the receptor element, altering its capacity to obstruct transcriptional read-through or the target sites for suppressor and mutator action. Short-range transposition of the receptor element within the locus may also be involved in some cases.

Transposition of controlling elements

A striking characteristic of controlling elements is their ability to move from site to site in the genome. Transposition of Spm, involving excision from one position and re-integration at another, is controlled by the mutator product of Spm, which seems to be effective only in the presence of suppressor activity[54]. Thus an active Spm can and does transpose itself autonomously, while an Spm that is inactive, as discussed below, remains fixed at one position.

While exicision of the receptor element of the Spm system is often seen, transposition has been reported in only one instance, that of the mutant wx_2^{m-8} (wx = waxy) derived from an a_2^{m-1} plant[57]. It should be noted, however, that transposition of the receptor element is common in other two-element systems in maize[3].

A model of Spm structure and functions

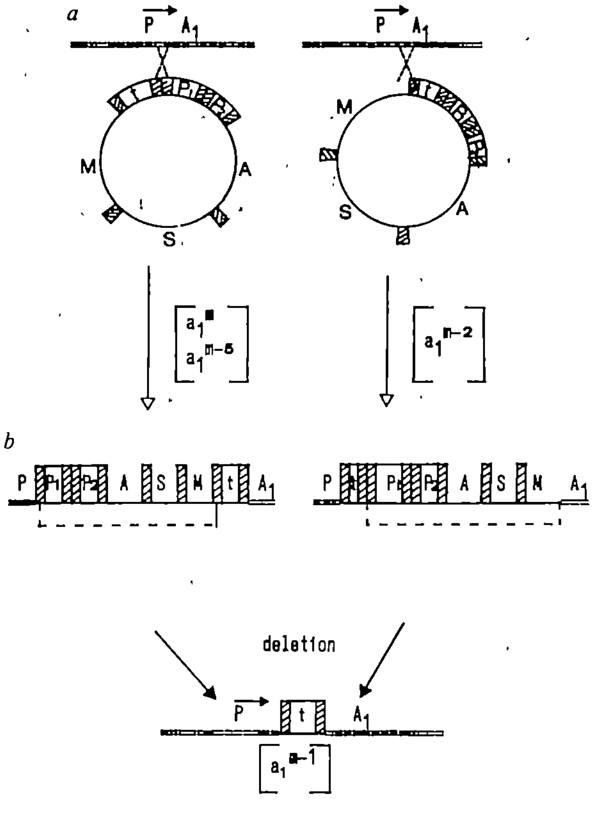
The repertoire of Spm activities is by no means exhausted by those described above. But before proceeding to a series of more subtle phenomena, such as cyclic changes in Spm activity and trans-activation, we wish to introduce a molecular model of Spm based on our knowledge of IS elements. It has been designed to fit a variety of observations into an intelligible framework and to promote discussion of new experiments.

The proposed molecular structure and functions of Spm are depicted in Fig. 3. The element includes three structural genes, one each for the suppressor and mutator products discussed above, and a third coding for a positive regulatory function, the activator, which will be discussed in the section dealing with trans-activation. There are two units analogous to IS2 at one end of the element, each with a promoter. At the other end is a unit similar to IS1, with a terminator sequence. Transcription can start spontaneously from P1, but transcription from P2 requires activation by the A gene product. The suppressor product of the S gene is envisaged as causing termination at the terminator sequence. The mutator product of the M gene executes excision at the indicated sites and induces alterations leading to new states, as discussed above. At the ends of Spm and interspersed throughout the element at various junctions are 'black box sequences', representing repeated sequences in reverse or direct orientation, comparable with those at the ends of bacterial transposons[37]. These sequences are not necessarily identical, but denote sites at which recombinational events such as inversions or deletions can occur.

Different modes of integration of Spm

By analogy with models of equivalent transposon processes, transposition of Spm can be considered as beginning with excision at the terminal sequences of the element, followed by circularisation and re-integration, as shown in Fig. 4(*a*). This process is catalysed by the mutator product. Integration at the site on the circular element between P1 and t gives mutants corresponding to a_1^{m-5} and a_1^m, in which the A locus is no longer expressed. Occasionally integration may take place at a different site on the circular intermediate, for example, the junction between M and t. This generates a mutant in which transcription started at the Spm promoter continues into the A1 locus. In this case, contrary to most situations described so far, the active element does not prohibit expression of the locus but promotes it. Obviously such mutants may be barely distinguishable phenotypically from wild type. However, if Spm is not transscribed, as in inactive phases described below, the mutant character is revealed, since no pigment is formed. This is exactly the case of the original mutant a_1^{m-2} (ref- 53) (Fig. 2, rows 8 and 9), which has been crucial to considerations of the molecular structure of Spm.

Fig. 4 *a*, Integration of Spm at the A1 locus in chromosome 3 of *Zea mays*, producing the mutant alleles a_1^{m-5}, a_1^m, and a_1^{m-2} whose phenotypes are depicted in Fig. 2. *b*, Possible origin of the receptor element from the alleles depicted in 4(*a*), leading to a two-element system.



Origin of the receptor element

Having established a model for Spm and mutants such as a_1^{m-5}/a_1^{m} and a_1^{m-2} caused by the integration of Spm into A1, let us now consider the origin of the receptor element in the Spm system. In a number of cases [7,51,52,53], a mutant harbouring a single, autonomous regulatory element at a given locus has generated derivatives in which only the receptor element is found at the locus, apparently accompanied by transposition of the regulatory element to another position. An explanation for this observation, which has been discussed elsewhere[58], is elaborated in Fig. 4(*b*).

When part of an integrated Spm is deleted, perhaps through inaccurate excision, the t unit may be left behind as a fragment that is still responsive to Spm, since it contains the target sites for both the suppressor and mutator functions. This is the situation found in the mutant a_1^{m-1} discussed earlier. When this residual unit is located between an A_1 structural gene and its promoter, transcriptional read-through may be reduced to some extent. However, when suppressor product is supplied by an active Spm, it acts at the terminator sequence of the receptor element to block transcription completely, just as the bacterial rho protein does at IS-sequences. The original level of expression of the locus can be restored when the receptor element is excised.

In addition to producing a receptor element corresponding to a complete t unit, as discussed above, partial deletion of Spm could also leave behind fragments that are greater or smaller than the t unit, resulting in various different states of the locus[8].

It is especially significant that the exceptional mutant a_1^{m-2} can generate a two-element system with a phenotype similar to the a_1^{m-1} phenotype described above[53]. This lends support to the proposal that the regulatory element in a_1^{m-2} mutants contains the same components as in other mutants such as a_1^{m-5} but in a different order, as shown in Fig. 4(*a*).

Cyclic changes in activity of Spm

An interesting property of Spm is its tendency to become inactive[54,59]. Inactive phases alternate with periods of activity with a characteristic frequency. Since an inactive element, expressing neither of its two products, occasionally becomes reactivated, these products do not seem to participate in such an activity change[54,60].

The effector of cyclic activity changes must be sought elsewhere, as shown by mutant alleles such as $a_1^{m(flow)}$ (ref. 59), which exhibit Spm activity only in certain parts of the kernel. The mutant $a_1^{m(flow)}$, has an Spm subject to activity changes at the A1 locus. In kernels of this mutant Spm is active only within a limited area at the base of the kernel. The element in the $a_1^{m(flow)}$ mutant is apparently sensitive to activating signals produced during the development of the base of the kernel.

In the terms of the molecular model of Spm, cyclic activity changes may result from inversion *in situ* of the promoters under the influence of extraneous signals, as in the inversion of IS2 discussed earlier.

Inversion of one or both promoters produces three different inactive structures, shown in Fig. 5. The result of inverting both promoters (Fig. 5*a*) is obvious. When only P2 is inverted, as in Fig. 5(*b*), RNA polymerase can still initiate transcription at the P1 promoter, but it will be obstructed if it collides with transcription machinery from the P2 promoter (see section on polar effects of IS2). When only P1 is inverted, as in Fig. 5(*c*), transcription of Spm from P2 can continue as long as activator product is present in the cell. The element will become inactive only when activator product in the cell has been sufficiently diluted. Because of this dilution requirement, it is unlikely that inversion of P1 is involved in somatic activity changes that occur during the development of a kernel. But an inactive structure of the kind shown in Fig. 5(*c*), is important for considerations of trans-activation, discussed in the next section.

Through the action of mutator product, an Spm regulatory element that exhibits a certain frequency of cyclic activity changes can mutate to alternate with a new frequency[60]. This indicates that something within the element itself determines the frequency (and time) of activity changes. These determinants are represented by the 'black box' sequences shown in the model in Fig. 3, at which inversion might occur. Mutational alteration of these sequences could affect the frequency of inversion.

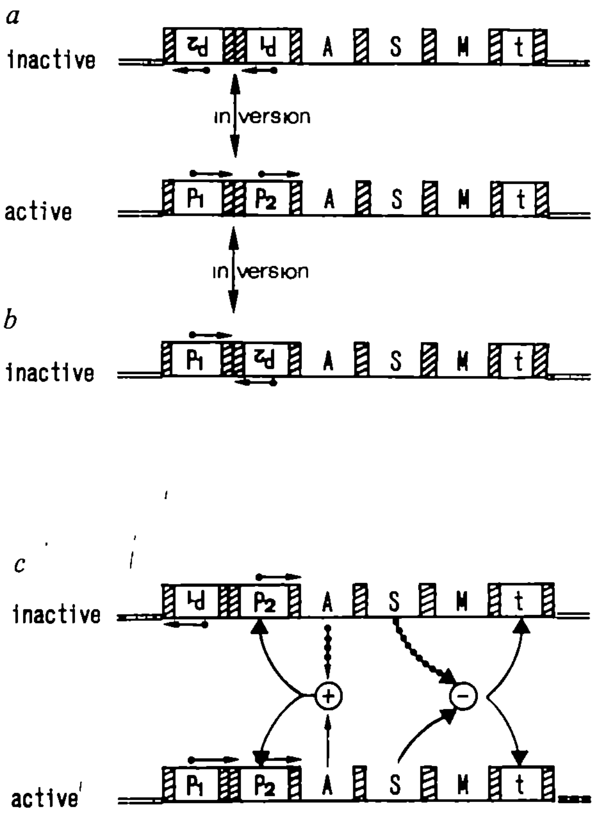


Fig. 5 Cyclic changes in activity of Spm. Inversion of one or both Spm promoters leads to three different inactive structures (*a*, *b* and *c*). The structure illustrated in *c* can be trans-activated when activator product is supplied by an active Spm.

Trans-activation of Spm

In a key experiment it has been demonstrated that an inactive Spm can be temporarily activated when a second fully functional Spm is introduced into the genome[60]. This was detected in a unique set of conditions which made possible phenotypic discrimination between kernels with double Spm activity and those with only one dose.

Normally when a receptor element is integrated at a locus, the same phenotype is produced regardless of whether one or more Spms are present in the genome. In one experiment, however, a special allele of a_2^{m-1} was used to test for Spm activity[55]. In plants with this allele the receptor element at the A_2 locus allows some pigment production when Spm is absent. In the presence of Spm suppressor product expression of the locus is eliminated and no pigment is produced. The unusual property of this receptor element is that it can no longer be excised in response to the mutator product. Thus in such a_2^{m-1} kernels, pigment is produced only in sectors in which Spm is missing or inactive; when two Spm are present, pigment is produced only when both are inactive. Since two inactivation events are less probable than one, a_2^{m-1} kernels with two Spms have fewer pigmented spots than those with one Spm.

With kernels containing the special a_2^{m-1} allele together with an active Spm, and one that is usually inactive for a longer period of time, one would expect to see a pattern of pigmented spots characteristic of a single, active Spm. But, surprisingly, kernels with a double dose phenotype are obtained[55], reflecting

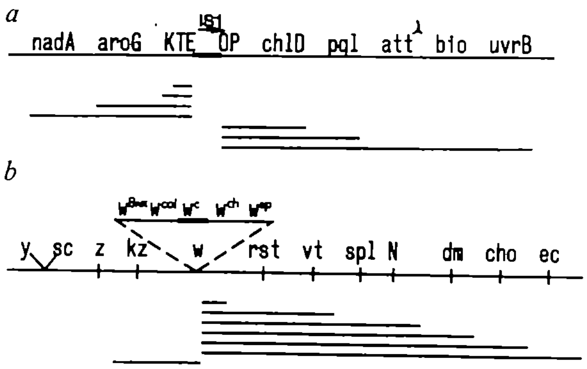

Fig. 6 *a*, Deletions induced by IS1 in the galactose operon of *E. coli* and (*b*) by the controlling element in the white locus of *D. melanogaster*. Data taken from refs. 47 and 64. Horizontal bars indicate extent of material removed in various classes of deletion derivatives

two active Spms. The originally inactive element is not turned on permanently in this process, however, and ceases to be expressed when its active counterpart is removed by meiotic segregation.

The observation of trans-activation implies a number of features of Spm, which have been incorporated in the model shown in Fig. 5(*c*). First, the temporary nature of the trans-activation suggests that it does not involve structural alteration of the inactive element. It follows that the S gene and a promoter for the S gene represented by P2 must be arranged in potentially transcribable orientation within the inactive element. The inactive condition of this element can then be accounted for by assuming that P2 is inactive unless stimulated by activator product, supplied in this case by an active Spm. For normal expression of Spm, a second promoter, P1 is proposed, from which transcription occurs spontaneously, leading to expression of the A gene. In addition, the double dose phenotype observed during transactivation indicates that each element is inactivated independently to produce pigmented spots. From this observation it can also be deduced that both the A gene and the S gene are situated downstream from P1 and P2, and that expression of the A gene triggers an autocatalytic cycle of expression of Spm.

Chromosomal rearrangements involving controlling elements

In the preceding sections we have summarised how the integration, excision, and transposition of elements of the Spm system and the action of certain Spm products function to control the expression of some loci in maize. But controlling elements, like IS sequences, have also been shown to enhance the incidence of inversions, deletions, and duplications of adjacent chromosomal regions, although much less attention has been devoted to this phenomenon. In maize, rearrangements of this kind have been observed in particular with the element dissociation[4]. There is evidence that elements resembling IS elements also occur in *Drosophila*[61,62], where they are frequently associated with chromosomal rearrangements. Detailed analysis of such processes has been facilitated by the many well-mapped genetic markers of this organism and by the banding patterns of its salivary gland chromosomes which permit visual detection of structural alterations. In one case, a transposable element seems to have been involved in a duplication of part of the white locus for eye colour[63]. An even more striking example is that of deletions found in association with another controlling element in the white locus of white–crimson mutants (Fig. 6*b*); in direct analogy to IS1 mediated deletion in bacteria, these deletions all start at the white locus and extend in either direction, ending at non-random points in the chromosome, resulting in distinct classes of deletion[64]. In this process the controlling element, like IS1, is retained in the deletion derivative where it can cause a second round of deletion[61].

The prevalence of IS sequences and controlling elements in organisms as diverse as *E. coli*, *Zea mays* and *Drosophila* suggests that they may be of general biological significance. There are, moreover, hundreds of other organisms that possess 'mutable genes', and exhibit phenotypes similar to those caused by controlling elements (see ref. 9). Furthermore, we have already noted that IS-sequences are natural residents of the wild-type *E. coli* chromosome, and there is evidence that controlling elements also exist at unknown positions of wild-type maize chromosomes, from which they can be 'dislodged' by irradiation[65], or mechanical disruption of the chromosome[4,5,66]. Whether they exert control functions at these positions or are simply kept in reserve as prefabricated units for the evolution of new control circuits remains unclear.

The large scale rearrangements found in association with such elements provide interesting grounds for speculation. Duplication, for example, is regarded by many as an indispensable process in evolution, producing a copy of genetic information with which mutational experiments can be conducted at lower risk and exempt from immediate selective pressure[67,68]. Inversions, deletions, and transpositions, on the other hand, may serve to create new nucleotide sequences or even new genes at fusion points. These processes may also represent important evolutionary means for reshuffling genetic information, uncoupling genes from old regulatory signals and linking them to new ones. This would provide adaptive flexibility while permitting conservation of vital or successfully evolved genetic information. Sequences analogous to IS sequences or their termini may serve as substrates for recombinational events leading to such rearrangements.

One recent observation suggests that chromosomal rearrangements may also play a part in differentiation. The variable and constant parts of the immunoglobin light chain seem to be coded by two different genes that are fused and expressed as a joint polypeptide[69]. In embryonic cells these genes seem to be separated, since they are located on different DNA restriction fragments. But in certain myeloma cells, which are thought to represent advanced developmental stages, arrested at a certain point, the two genes are found on the same DNA fragment. This has been interpreted to mean that fusion of these genes occurs curing development through deletion of the intermittent material, inversion, or transposition.

We are especially grateful to Drs B. McClintock and P. A. Peterson for critical reading of the manuscript and for many helpful discussions leading us to a deeper insight into controlling elements.

Protein–DNA and protein–hormone interactions in prealbumin: a model of the thyroid hormone nuclear receptor?

C. C. F. Blake and S. J. Oatley

Laboratory of Molecular Biophysics, Department of Zoology, South Parks Road, Oxford UK

High resolution X-ray analysis of the hormone-binding protein prealbumin has shown that it has a structural complementarity to double-helical DNA. The proposed binding site is composed of two symmetry-related β-sheets containing a pair of helically disposed arms, which can interact with the bases in the wide groove of DNA. A palindromic target sequence is indicated by the symmetry of the protein. The two identical thyroid hormone binding sites on prealbumin are located in a channel that runs completely through the molecule. These two structural features suggest prealbumin as a model for the thyroid hormone nuclear receptor, providing a number of detailed predictions of its properties.

The generally accepted model for the expression of hormone activity gives a central role to the hormone receptor. Receptors are presumed to be proteins that have two essential properties: the ability to form extremely tight and specific complexes with particular hormones, and the ability to convert the interaction into a signal that initiates the response of the target cell. Although the receptors for many hormones are located in the outer membrane of the target cell, there is increasing evidence that at least one class of receptor for the thyroid hormones is located in the cell nucleus[1-4]. Since these hormones exert their effects primarily on gene expression, it seems probable that their receptors may be able to initiate this response through binding to the double-helical DNA in chromatin, but little is known of their mode of action at the molecular level.

The thyroid hormones are water-insoluble molecules that require specific binding proteins in the plasma and the cell cytosol to enable them to gain access to the nuclear receptors. In an attempt to define the nature of the interactions between the thyroid hormones and their binding proteins, we have been working on the X-ray structure of prealbumin, one of the two thyroxine-binding proteins in human plasma. Prealbumin has a molecular weight of 55,000 and is composed of four identical subunits of 127 amino acid residues[8], arranged with tetrahedral symmetry[5]. The protein has two hormone binding sites whose association constants[9] for L-thyroxine (T_4) are 1.05×10^8 M^{-1} and 9.55×10^5 M^{-1}; triiodo-L-thyronine also binds at these sites about an order of magnitude less strongly. The X-ray results indicate that these two sites are structually identical and are deeply buried in a narrow cylindrical channel that runs through the centre of the protein molecule. Prealbumin also carries independent binding sites for retinol-binding protein (RBP) (ref. 10), the specific plasma carrier of vitamin A. There are apparently four equivalent binding sites for RBP (ref.11), but information on their location and interactions is at present lacking.

We have now discovered, however, that part of the surface of the prealbumin molecule is complementary in size and shape to the stable B-form of double-helical DNA. This putative DNA-binding site, which has the form of a deep semi-cylindrical groove equipped with a pair of helically disposed arms, is constructed almost entirely from a symmetry-related pair of β-sheets. Although in principle the great diversity of protein structure allows binding sites for any ligand to be constructed, no detailed model of an interaction between native, double helical DNA and a globular protein has yet been proposed. The site we observe is almost entirely composed of regular protein structure, and therefore provides a general model for protein–DNA interactions, especially as the mode of binding that is indicated incorporates many of the features that have been proposed for such interactions[12].

Because prealbumin has no known function that may involve DNA binding, nor as a soluble plasma protein is there any compelling reason to anticipate such a function, the significance of the structural complementarity to DNA is not immediately obvious. In particular, we cannot rule out the possibility that the site is merely a coincidental feature of the molecular structure, without biological significance. But the closeness of fit and the mode of interaction with the standard DNA double helix suggest that we should seriously consider the alternative possibilities that either prealbumin has so far undetected DNA-binding function, or that it is related to a protein that does have such a function. Of these possibilities the first can be tested either by careful model building of the proposed prealbumin-DNA complex or by direct binding studies, while the second can only be approached at present by speculative arguments. Nevertheless we feel justified in considering the second possibility in more detail because, as the one known protein whose function combines both thyroid hormone and DNA binding, the thyroid hormone nuclear receptor is the most obvious potential relative of prealbumin, implying that the interactions we observe in prealbumin may shed some light on the properties of the receptor itself about which little is otherwise known. These considerations lead us to interpret the presence of a DNA binding site on prealbumin as indicating the possibility that some or all of the thyroid hormone binding proteins belong to a family whose members have evolved from a common ancestor, and in particular that prealbumin and the receptor have evolved from an ancestral protein whose structure encompassed both hormone and DNA binding sites. Evidence for a relationship between prealbumin and the other known thyroid hormone binding proteins (the receptor and the plasma protein, thyroxine-binding globulin, TBG) is limited by our lack of knowledge of the characteristics of these proteins, especially of their amino acid sequence. The only known properties of the receptor, its molecular weight[13] and the general chemistry of its hormone binding site [14], are similar to prealbumin; while prealbumin and TBG share the same molecular weight, subunit structure, single strong T_4 binding site per tetramer, and the same extreme stability towards denaturants[15]. Although this evidence is circumstantial and meagre, it does lend some support to the proposal. We therefore present the details of the protein–hormone and protein–DNA interactions in prealbumin for consideration as a model of the thyroid hormone nuclear receptor. The model predicts a number of verifiable properties of the receptor, including its molecular properties, the nature of its hormone and DNA binding sites, and a possible pathway of interaction between them.

X-ray analysis

A preliminary description of the tertiary and quaternary structure of the prealbumin molecule determined from a 2.5-Å resolution Fourier map phased with three isomorphous derivatives has been reported[16]. Following this preliminary analysis the complete amino acid sequence of prealbumin has been determined[8], and readily incorporated into the X-ray model. This model has now been partially refined against 1.8-Å resolution X-ray data—the practical limit of the diffraction pattern—to give an overall R factor of 29% for the 24,000 unique reflections, where

$$R = \frac{\Sigma \,\|F_{\mathrm{obs}}| - |F_{\mathrm{calc}}\|}{\Sigma\, |F_{\mathrm{obs}}|} \times 100$$

Although the refinement is being continued, the present stage enables us to give a reliable picture of the molecule and its binding sites.

The prealbumin monomer is a classic 'β-barrel' molecule, with eight β strands organised into two four-stranded sheets. The whole molecule is a tetramer with subunits arranged tetrahedrally. The β sheets represent the major points of subunit interaction: monomers associate into dimers by antiparallel hydrogen bond interactions between equivalent sheets giving the dimers two eight-stranded sheets; the dimers associate in the whole molecule by opposing equivalent eight-stranded sheets face-to-face in the centre of the molecule. The prealbumin molecule shown in Fig. 1 is therefore a very simple structure composed of four eight-stranded β sheets—an 'inner' pair sandwiched between an 'outer' pair. A remarkable feature of the structure is that the inner sheets are not in contact but form, or are separated by, an open channel that runs through the molecule.

Low resolution X-ray analysis[11] of prealbumin complexed with its hormone ligands, T_3 and T_4, has shown that they are located at two symmetry equivalent sites located deeply within the central channel. As with some other proteins, it has proved difficult with prealbumin to define conditions in which the ligands will bind reliably in the crystals. We suspect the reason for this is the very low solubility of the hormones in the mother liquor of crystallisation, but whatever the reason, we have so far been unable to collect the high resolution three-dimensional X-ray data that is needed fully to define the nature of the

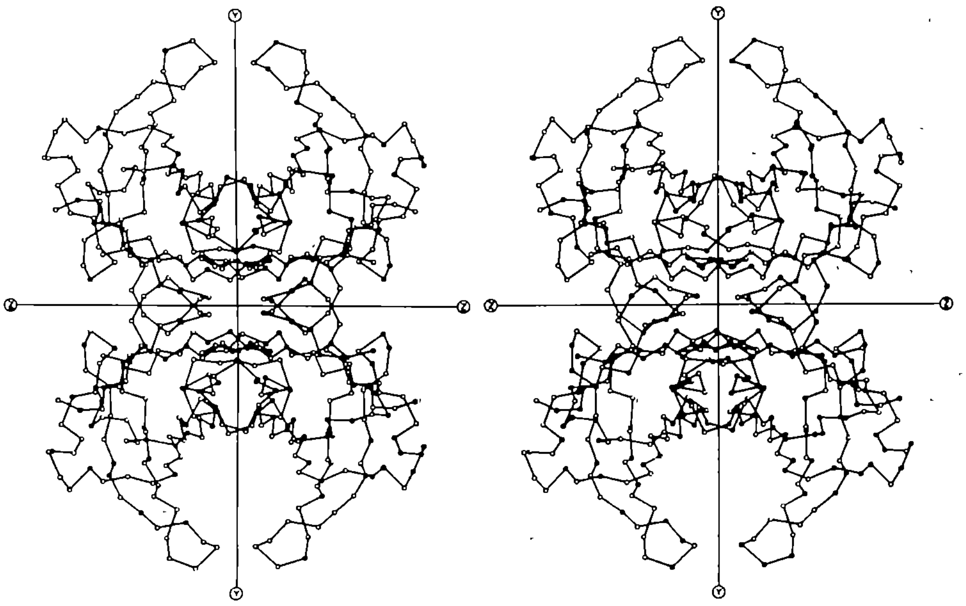

Fig. 1 A stereo drawing of the α-carbon positions of the prealbumin tetramer looking down the molecular x axis. The hormone binding sites are located in the channel that runs horizontally through the molecule parallel to the z axis. The proposed DNA binding sites are located at the top and bottom of the figure, so that the DNA is located with its helix axis parallel to x.

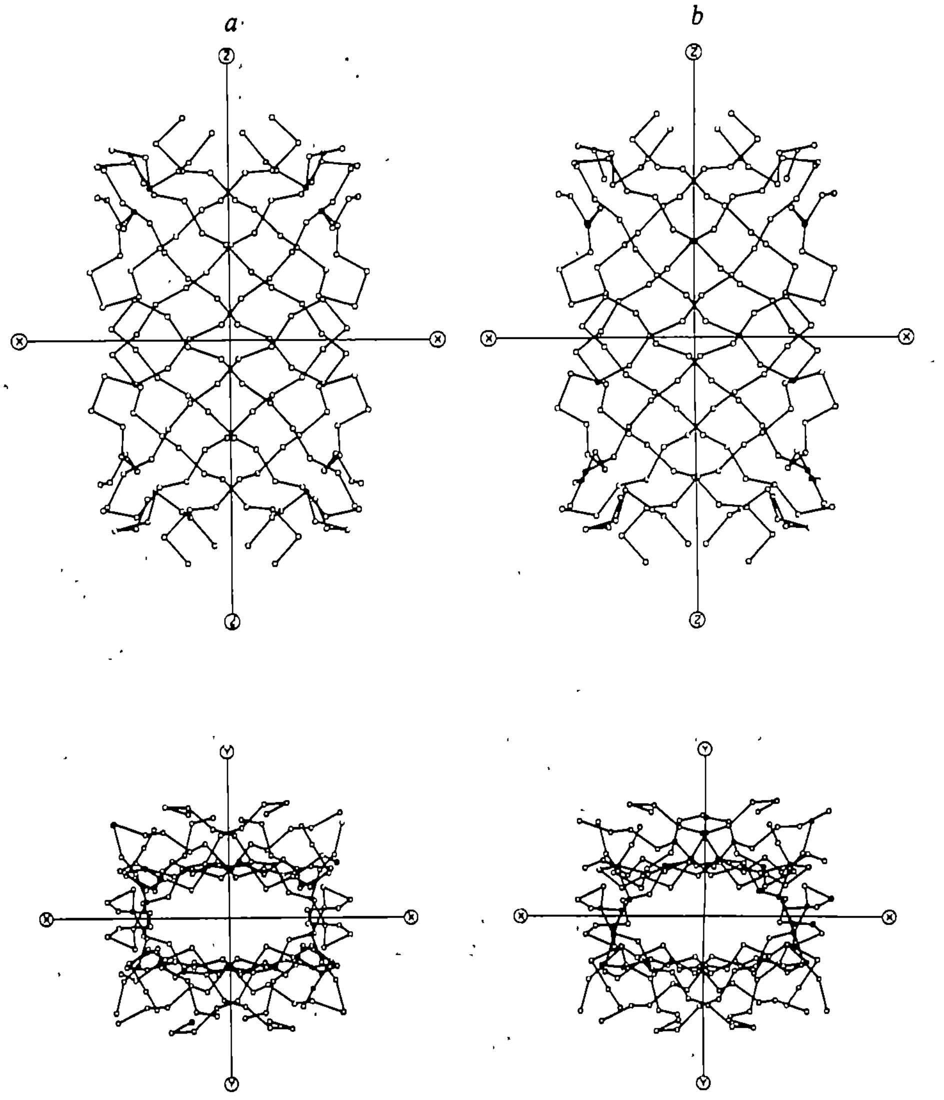

Fig. 2 Stereo diagrams showing the organisation of the polypeptide chains of the four subunits around the central channel; *a*, looking down the *y* axis; *b*, looking down the *z* axis. The circles represent carbon positions.

protein interactions. However, we have been able to collect high resolution data in projection that seem to give results fully consistent with the previous low resolution three-dimensional maps.

The thyroxine binding site

The central channel that contains the thyroxine binding sites can be seen in Fig. 1 running horizontally through the centre of the molecule. Stereo views of the local structure of the channel are shown in Fig. 2, looking down the *y* axis and the *z* axis (the axis of the channel). The surface of the channel is tightly organised from the polypeptide chains of the inner, four stranded β sheet of each of the four subunits, and takes the form of a 16-stranded β cylinder about 50 Å long. The molecular 222 symmetry divides the channel into two symmetry-related halves clearly showing that the two binding sites are identical. In addition one of the molecular twofold axes coincides with the channel axis showing that each site itself has twofold symmetry. Figure 3 shows one half of the channel with the side chains that project into it. The chemistry of the channel is characterised by three elements arranged linearly along it, which reading from the centre are: (1) a hydrophilic patch formed by the hydroxyls of the Ser 117 and Thr 119 pairs of residues; (2) a hydrophobic patch formed by the methyl groups of the Leu 17, Thr 106, Ala 108, Leu 110, Thr 119 and Val 121 pairs; and (3) a group of charged residues including the paired side-chains of Lys 15, Glu 54 and His 56. The absence of any of the molecule's 48 hydrophobic aromatic residues from the channel is both clear and striking. An analysis of the free space around the axis of the channel was carried out by calculating van der Waals cross sections in 1-Å thick sections along its length. The analysis showed that there is a cylindrical hole along its length with a fairly constant diameter of about 8 Å, except at two symmetry-related positions some 4 Å on either side of the centre of the channel where the close approach of the paired side chains of Leu 110, Ser 115 and Ser 117 cause a marked local constriction.

The low resolution X-ray analysis of complexes of prealbumin with both T_3 and T_4, showed that the hormones are bound exclusively at two symmetry-related sites buried deeply within the central channel (see Fig. 8 of ref. 16). The difference electron-density envelopes for both ligands were elongated along the axis of the channel and extended from about 4 Å from the centre to about 16 Å. Interpretation of these features suggest that the two hormones are bound in much the same way, located between the constriction near the Ser 117–Thr 119 pairs of side chains and the Lys 15–Glu 54 pairs of charged residues, with their long axes more or less parallel with the axis of the channel. The identity of the two binding sites by symmetry confirms the proposal[8,17] that the difference in binding constants implies negative co-operativity between the sites. The constriction observed near the centre of the channel would prevent access from one binding site to the other, indicating that the interactions are of the site–site rather than ligand–ligand type (compare refs 9 and 17).

The 3-Å resolution projection maps of the ligands have been used to attempt to locate the iodine substituents of the hormones within the overall electron-density envelopes observed in the low resolution maps. Although fully self-consistent results have been obtained, projection maps of proteins can be very misleading and the interpretations given below must be regarded

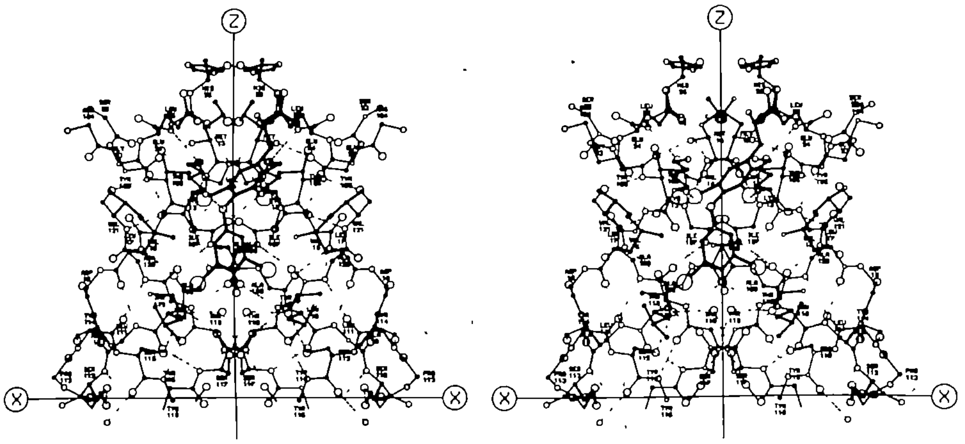

Fig. 3 Stereo diagram of the atomic arrangement in a single hormone binding site. This drawing corresponds to the upper half of Fig. 2(*a*). The main chain is shown in light line and side chains that point into the site are shown in medium line. The position of the T_4 molecule, shown in heavy line, was derived by fitting the coordinates of Cody[14] to the iodine positions indicated in the projection maps.

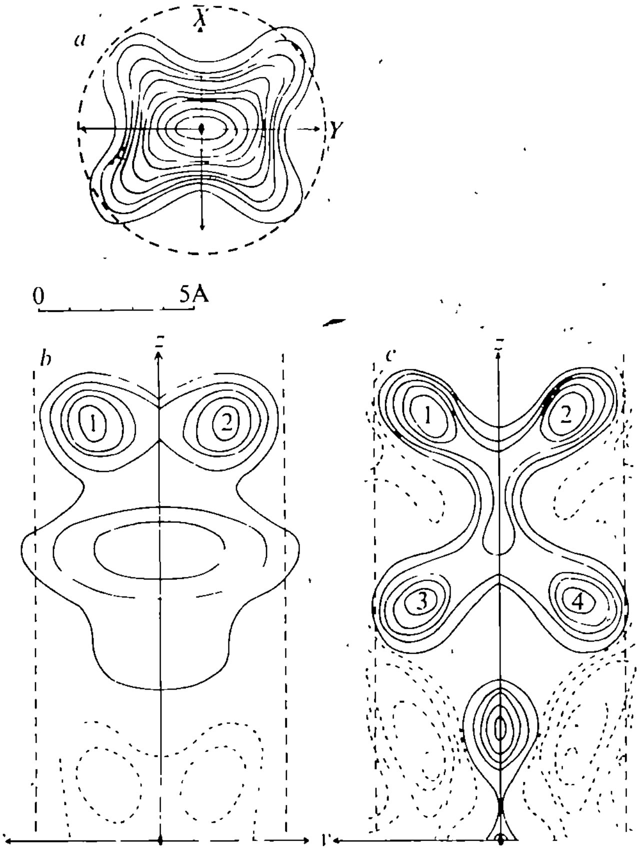
as provisional until three-dimensional high resolution data on ligand binding is obtained. The difference map of T_3 binding projected down the *z* axis (the axis of the channel and approximately the long axis of the hormone) is shown in Fig. 4*a*. It can be interpreted as indicating that the benzenoid rings of the hormone are roughly at right angles as expected (the bulky iodine substituents cause other orientations to be energetically unfavourable), and are orientated at about 45° to the molecular *x* and *y* axes. The equivalent maps of T_3 and T_4 projected down the *x* axis shown in Figs 4*b* and *c* contain discrete peaks consistent with Fig. 4*a*, that can be interpreted as representing the various iodine substituents of the hormones. It can be seen that the pairs of peaks labelled 1 and 2 further from the centre of the channel are coincident in both maps, but that the inner pair labelled 3 and 4 in the T_4 map is replaced by a diffuse region of density in T_3. The simplest interpretation of the two maps is that the common pair of peaks represent the 3,5 pair of iodines in each hormone, that the inner pair of peaks in T_4 represent its 3′,5′ pair of iodines, and that the diffuse density in T_3 represents alternative positions of its single 3′-iodine.

Fig. 4 3-Å resolution difference maps of the binding of (*a*) T_3 projected down the *z* axis; (*b*) and (*c*) T_3 and T_4 respectively, projected down the *x* axis. Contours are at equal but arbitrary levels; positive in full line, negative in broken line. The confines of the channel, assuming a constant diameter of 8Å, are shown in heavy broken line.



Taking the interpretations of the projection maps together it is possible to define a tetrahedron of iodine substituents for T_4 that is generally consistent in size and geometry with that found in the structures of the crystalline hormone[18,19]. However, to obtain the points of interaction between the iodines and the protein, an ambiguity concerning the orientation of the tetrahedron—are the peaks 1 and 4 of Fig. 4*c* above the plane of the projection and peaks 2 and 3 below, or vice versa—has to be resolved. A provisional solution has been achieved by finding that one orientation can be fitted in the channel without producing unacceptably close contacts with the protein, but that the other cannot. Assuming the former orientation to be correct (shown in Fig. 3) each pair of iodines can make favourable hydrophobic contacts with protein side-chains. Each of the 3′,5′-iodines lies between and in contact with the side chains of Leu 17 and Leu 110, and each of the 3, 5-iodines fits into a pocket lined with the methyl groups of Thr 106, Ala 108 and Val 121 and the β- and γ-methylenes of Lys 15. These positions are also consistent with the interaction of the hormone's 4′-hydroxyl, through a well defined water molecule, with the hydroxyls of the Ser 117 and Thr 119 pairs of residues in the hydrophilic patch, and with the interaction of the hormone's α-carboxylate and α-amino group with Lys 15 and Glu 54 respectively. This latter interaction, and with it the broad outline of this proposal for hormone binding, is strongly supported by affinity labelling experiments on prealbumin using dansyl chloride[20] (a competitive inhibitor of T_4) and bromoacetyl-T_4 (ref. 21), both of which have been found covalently attached to Lys 15.

The DNA binding site

Our attention was drawn to the possibility of a DNA-binding site on prealbumin by the remarkable cylindrical–helical depression in the outer surface of the molecule, shown in Fig. 1. This site is formed by the 'outer' β sheets of two symmetry-related subunits. The normal right-handed twist of the sheets coupled with the symmetry induced by the molecular twofold axis parallel to *y* gives rise naturally to a concave cylindrical structure, that is given its helical character by the extended hairpin loops made by the two outer strands of each sheet. The structure so formed has a length of about 40 Å, a diameter of about 25 Å and a helical pitch of about 33 Å.

The extent to which this site is complementary to double-helical DNA was explored by model building, using an interactive computer display system[22]. The coordinates used were those of the main-chain atoms of prealbumin from the latest stage of refinement, and a standard set for all the atoms of the B form of the DNA double helix[23]. These coordinates were maintained throughout the fitting, which therefore corresponded

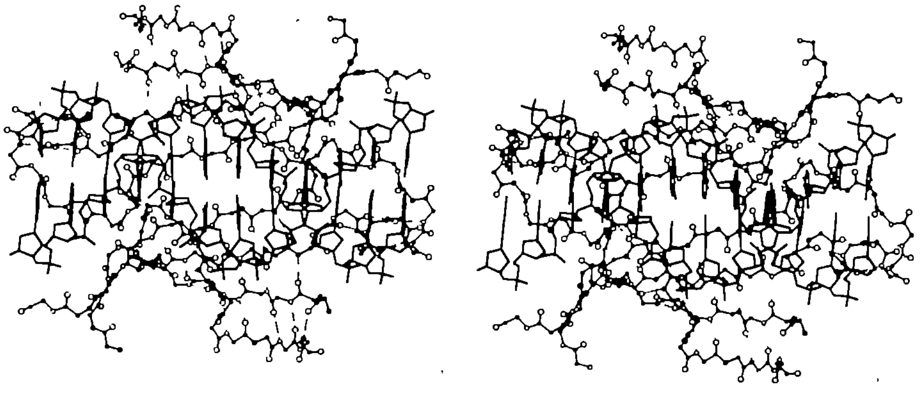


Fig. 5 Stereo diagram of the proposed prealbumin–DNA complex looking down the *y* axis, with the *x* and *z* axes horizontal and vertical respectively. The main chain atoms of the outer β-sheet are shown in light line with the hydrogen bonds in broken line. The DNA is drawn in heavy line. All the atoms in the diagram are related by the twofold axis parallel to *y* that is positioned at the centre of the diagram.

to the mating of two rigid molecules. The first step in locating the DNA in the site was carried out by making the molecular *y* axis of the protein coincide with one of the twofold axes of the DNA helix that runs between each base pair perpendicular to the helix axis. When the protein and DNA twofold symmetry axes coincide, only two degrees of freedom remain: rotation of the DNA around the axis relative to the protein, and translation of the DNA along the axis relative to the protein. Rotation of the DNA around the axis was seriously restricted by the helical arms to a narrow range of orientations in which the DNA helix runs closely parallel to the axis of the cylindrical channel. In this orientation the helical arms of the protein fit closely into the wide groove of the DNA double helix. A rotation of 180° from this orientation—the only alternative position—is not as favourable because the helical arms are too large to fit into the narrow groove of the DNA. Translational adjustment of the DNA along the common symmetry axis was relatively easy because it corresponds to bedding the DNA down the channel, making due allowance for the protein side chains.

The final fit of the DNA to prealbumin obtained from the computer display is shown in Figs 5 and 6. Its characteristics are as follows.

(1) The twofold axis of symmetry of the protein coincides with the twofold axis of symmetry in the DNA.

(2) The DNA double helix lies in the pronounced cylindrical depression in the protein molecule with its helix axis parallel to the axis of the depression.

(3) The pair of helical arms of the protein fit closely into the wide groove of the DNA double helix. This is the most striking feature of the fit because it could allow the arms to interact with the DNA bases whose edges are exposed in the wide groove. We therefore consider that the helical arms can act as 'reading heads' that probe the DNA for a compatible base sequence. The twofold symmetry relation of the arms would necessarily imply that such compatible base sequences must be palindromic. But Fig. 5 shows that this is not necessarily true for the two base pairs at the very centre of the binding site which are in fact more distant from the protein surface than the base pairs on either side. This relieves the requirement for an exact palindrome at the centre of the interaction site as has been observed for the *lac* operator[24] and the *Haemophilus* endonuclease specificity site[20].

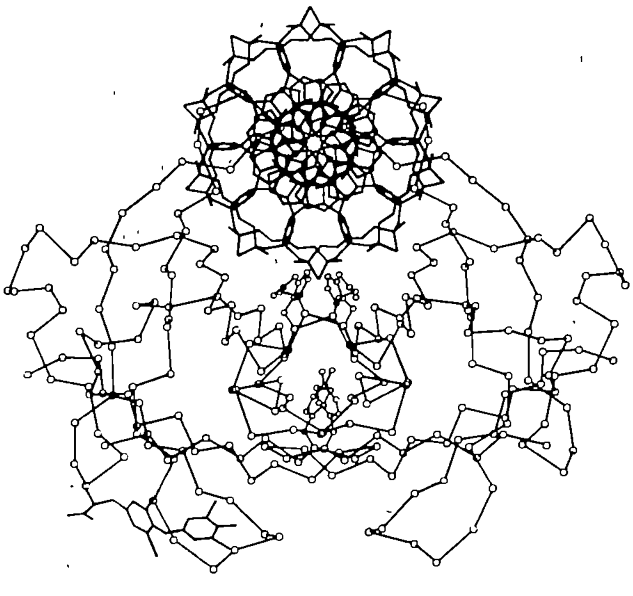
We have not yet carried out the careful model building of DNA in the proposed site on prealbumin that might tell us whether the protein, in addition to having an appropriate structure, also has the appropriate side chain distribution for favourable interaction with DNA. At present, therefore, we can only note that the proposed binding site on the protein is especially rich in ionic side chains; ten lysines, four histidines, eight glutamates and six aspartates are located in positions where they could interact with some part of the DNA. In addition Trp 41 is located in a totally exposed position on the helical arms with its indole ring parallel to and between neighbouring base pairs, suggesting that intercalation should be considered in any possible scheme of interaction.

Finally, any model of a hormone nuclear receptor should indicate the possibility of a means of communication between the hormone and DNA-binding sites. That some structural response to thyroxine binding takes place in the prealbumin molecule is indicated by the negative cooperativity of binding. The nature of this structural response, which may alter the geometry and properties of the DNA-binding site, can be determined by high resolution X-ray studies of hormone binding. In the absence of these studies we can only note that the separation and orientation of the symmetry-related pairs of β-sheets that form the DNA site, could be controlled by Tyr 116 (whose position is shown in Fig. 6) whose hydroxyl is inserted between the inner strands of the two β-sheets, forming a hydrogen-bond bridge between them. The residue following this tyrosine, Ser 117, is located in the hormone binding site and is hydrogen bonded through a water molecule to the 4′-OH of thyroxine. Although there may be other possibilities, Tyr 116 is the most obvious means of communication between the sites, because it is uniquely situated with its peptide involved in the β-structure of the hormone binding site and its hydroxyl involved in the hydrogen bonding network of the β-sheets that form the DNA binding site.

Conclusions and predictions

The most important general conclusion from this work is that the typical binding site depression of a globular protein molecule

Fig. 6 A drawing of the proposed prealbumin–DNA complex looking down the *x* axis, with the *y* and *z* axes vertical and horizontal respectively (compare with Fig. 1). The main chain of the prealbumin dimer is shown in light line; the circles represent the α-carbon positions. The symmetry-related pair of tyrosines 116 are shown at the lower centre, and two pairs of side chains that point into the DNA binding site are shown in the centre. The DNA double helix is seen end-on in heavy line at the top, and one T_4 molecule in its (half) site is drawn in heavy line at the lower left.



can take on the helical character necessary for combination with native DNA when the binding region is composed of a symmetry-related pair of β-sheets. If the outer strands of the sheets 'peel off' from the body of the protein, as occurs in prealbumin and also, in different contexts, in a number of other β-structured proteins, a pair of helically-disposed 'arms' are formed that can fit into the grooves of the DNA double helix where they can probe the nucleotide bases for a complementary sequence. As a consequence of the twofold symmetry of the site, the complementary base sequence must necessarily correspond either to an exact palindrome or alternatively to a palindrome with a gap at its centre. The latter case arises because the arms fit the outer parts of the target sequence more closely than its centre. Although the particular structure of prealbumin suggests a potential interaction with a six or eight base palindrome, it can easily be extended to provide a general basis for protein–DNA interaction, that can account for the four-base palindromic target sequences of some restriction enzymes[26–28] and the 20-base 'gapped' palindrome of the *lac* operator[24]. Details of this general model will be published elsewhere.

In prealbumin the thyroxine binding sites are located deeply inside a cylindrical channel that runs completely through the molecule. When bound at these sites the hormone is almost completely removed from the surrounding medium. The binding sites have twofold axial symmetry to which the hormone is surprisingly well-suited and provide individually favourable microenvironments for each of the characteristic substituents of the hormone. Minor side-chain substitutions in a site of this kind, such as possibly the inclusion of aromatic residues at the iodine binding sites, could readily account for the very tight binding exhibited by receptors.

Finally we consider the possibility that the presence of a potential DNA-binding site, in addition to its thyroxine site, makes prealbumin a useful model of the thyroid hormone nuclear receptor. This possibility can be tested by verifying or contradicting the following predictions on the properties of the receptor that can be derived from the model: (1) it is a tetramer; (2) it is unusually stable and not easily dissociated into subunits; (3) its polypeptide chain is largely organised into β-structure; (4) it has two hormone binding sites; (5) it interacts with a segment of DNA 10–12 base pairs in length; (6) this segment contains a palindromic sequence of six to eight bases. Two other properties of the receptor, its molecular weight[18] and the linear arrangement of hydrophilic, hydrophobic and ionic groups in its hormone binding site[14], are not included in these predictions because they have already been determined, and are in agreement with the model.

This work was supported by the MRC. We thank Drs DeW. S. Goodman and R. E. Canfield of Columbia University, and Drs G. Gonzalez and R. E. Offord of Oxford for providing sequence information on prealbumin before publication, and Drs J. Robbins of NIH, Washington and E. C. Jorgensen of the University of California for useful discussions. We also thank Andrew Dearing for providing DNA coordinates.

The net membrane current of the electrically excitable membrane of Paramecium *during step depolarisations was measured using voltage-clamp techniques. The mutant, pawn B, lacks a functional Ca channel. Thus the difference between the total current measured in the wild type and the leakage and rectification currents measured in the pawn mutant is the Ca current. These findings were confirmed by ion substitution experiments. The possibility that inactivation may be apparent only, and caused by a hypothetical, superposed, Ca-induced, rectifying K⁺ current was eliminated.*

IN an attempt to study the molecular biology of excitable membranes in ways not possible in nerve, behavioural mutants with defective membrane functions have been isolated in *Paramecium*. *Paramecium* is a unicellular animal which swims by beating its cilia. The direction of its ciliary beat is controlled by the electrically excitable membrane[1,2]. Extensive electrophysiological studies produced evidence of the existence of Ca and K channels in the *Paramecium* membrane[3–8]. One of the difficulties of membrane-physiological investigations in general is that only the net transmembrane current or the voltage change due to this current is measured by the electrode. Analysis of the properties of

a single kind of channel requires a separation of different ion currents. Traditionally, this is done with drugs or by ion substitution[10,11]. The same purpose can be accomplished by genetic means. We separate the inward Ca^{2+} current by comparing the total current in wild-type *Paramecium* and that in a mutant which lacks a functional Ca Channel[4,9]. To measure the total membrane current, we use constant voltage pulses during step depolarisations. We find that the Ca current inactivates in time, similar to the Na currents described in nerve[12] but different from Ca^{2+} currents described in barnacle muscle[13] and at the squid giant synapse[14]. This finding is supported by ion substitution experiments done on single wild-type cells. Suspicions are removed that the apparent time course of the Ca^{2+} current may be partially masked by a Ca-induced K^{+} rectifying current.

Wild type compared with the mutant 'pawn'

When wild-type paramecia hit a physical obstacle or enter an undesirable ionic environment, they avoid it by swimming backwards for a short distance and then swimming forwards again in a different direction[15]. The electrical excitability of the membrane controls backward swimming. A small depolarisation results in a graded action potential whose inward current is carried by Ca^{2+} (refs 3, 5). The increase in internal Ca^{2+} concentration then causes the cilia to reverse the direction of their power stroke (ciliary reversal) by a yet unknown mechanism[16].

Named after the chess piece, 'pawns' are mutants which cannot swim backward[17,18]. Electrophysiological studies traced the defect of these mutants to the malfunction of the Ca channels[4,9].

Paramecium tetraurelia, previously known as *P. aurelia*, species 4 (ref. 19) was used in these experiments. The wild type was stock 51S and the pawn mutant was stock d4-95, genotype *pwB pwB* (refs 4, 17). Voltage was clamped using standard techniques[20]. Cells, in a buffer solution containing 1 mM CaCl$_2$, 1 mM HEPES (Sigma), 0.5 mM KOH, 3.5 mM KCl, 10^{-7} M EDTA, *p*H 7.0, were impaled with microelectrodes filled with 3 M potassium acetate and having a resistance of 10–15 MΩ The potential was held at resting level and stimulus pulses were given at a frequency of about 1 Hz. The voltage stabilised at the command level 500 to 1,000 μs after a step change in the command. At the end of an experiment the voltage-measuring electrode was withdrawn to measure the reference potential. Activation of the Ca^{2+} inward current is fast, so that the beginning of activation could not clearly be seen, even in the best preparations. It is technically difficult to get stable preparations of *P. tetraurelia* with the low resistance electrodes which are required if the potential is to be changed quickly enough to see inward currents clearly.

Sample traces are shown in Fig. 1. The current traces from wild-type cells (Fig 1*a*, *c*) show a transient inward current lasting about 5 ms and then a steady-state outward current in response to a step depolarisation. A step depolarisation of pawn cells results in a steady-state outward current but there is no detectable inward current (Fig. 1*b*) even when viewed at high gain (Fig. 1*d*). Steady-state outward currents of pawn and wild type are not detectably different over the range of voltages studied (Fig. 2), and the voltage dependence of both peak and steady-state currents is similar to that in *P. caudatum*[21]. Depolarisations to nearly 0 mV from the resting potential of ~ -23 mV result in a transient inward current and a steady-state outward current whose magnitude is about equal to that of the leakage current. Steady-state outward currents increase steeply as a function of voltage for step depolarisation above 0 mV. As in other excitable membranes, this voltage-dependent outward current is called the delayed-rectification current, and it is probably due to the opening of K channels. At large depolarisations the outward current activates so rapidly that the inward current cannot be seen clearly.

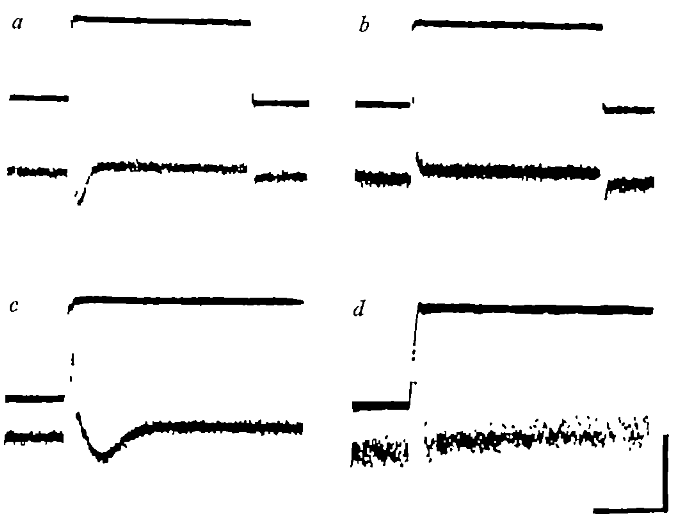

Fig. 1 Sample traces of voltage-clamp experiments in two strains of *Paramecium tetraurelia*. *a*, *c*, Records from wild type; *b*, *d*, records from the mutant 'pawn' cells. In each case the upper trace shows the voltage and the lower trace shows the associated current. In (*a*), a transient inward current is followed by a steady-state outward current. Record (*c*), from a different cell, shows a similar event at greater sweep speed. Record (*b*), and (*d*) show that pawns lack the transient inward current; (*d*) is recorded at higher gain and faster sweep than (*b*). Calibration: *a* and *b*, 20 mV, 10 nA, 10 ms, seven superimposed sweeps; *c*, 20 mV, 10 nA, 4 ms, 10 superimposed sweeps; *d*, 20 mV, 5 nA, 4 ms, 10 superimposed sweeps. Holding potentials are 20 mV, 24 mV, ? mV, and 25 mV for *a*, *b*, *c*, and *d*, respectively.

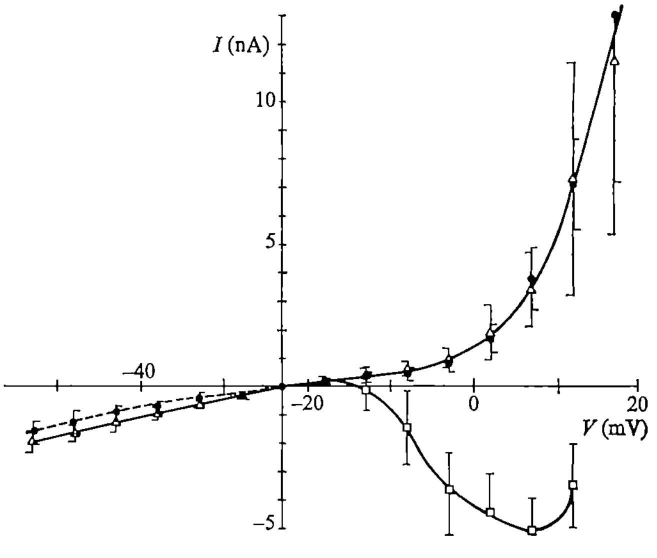
Pawn lacks a transient inward current, but there is no measurable difference in the characteristics of the steady outward currents between pawn and wild-type cells. The time courses of the transient inward current alone can be calculated by subtracting leakage and rectification currents as measured in pawn from the total current measured in wild type. Figure 3 shows one such calculation for cases with minimal rectification.

Fig. 2 Voltage–current relationship of peak inward (□) and steadystate outward (△) currents of wild type, and steady-state outward (●) current of pawn mutant. Steady-state outward currents were measured 25 ms after the beginning of depolarising pulses. Minimum inward currents resulted from hyperpolarising pulses. Data were taken from four wild-type cells with holding potentials 23±5 mV (mean ± s.d) and five pawn cells with holding potentials 23±3 mV. Points and bars represent mean current magnitudes ± s.d. Where the slope of the curve is greater, standard deviations are larger. There is no significant difference in the steady-state outward currents between the two stains.



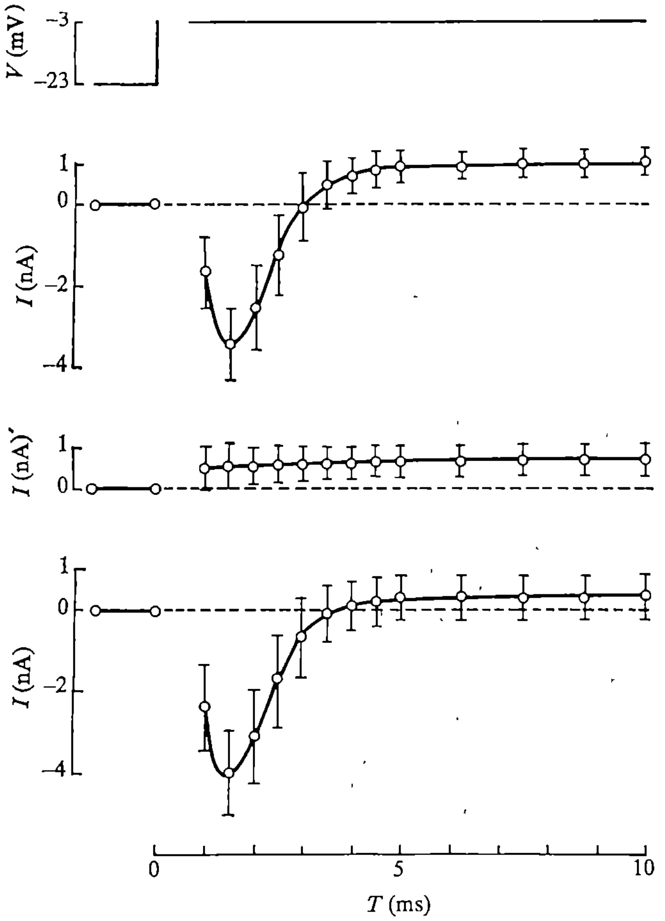


Fig. 3 Average time course of currents associated with step depolarisations of 20 mV in wild type (*a*) and pawn (*b*). Mean current magnitudes ± s.d were measured at various times from the same four wild-type cells and five pawn cells whose voltage–current characteristics are shown in Fig. 2 *c* shows the difference between current measured in wild type (*a*) and pawn (*b*) ± s.d. of the difference of the means. Measurements were not made in the first 1.0 ms after the step depolarisation because the voltage was not well controlled during this time.

Variation in measurements makes the comparison of single cells unreliable, so average time courses of membrane currents were determined from four wild-type cells (Fig. 3*a*) and five pawn cells (Fig. 3*b*) after a 20-mV step depolarisation. The difference of the two time courses (Fig. 3*c*) shows the time course of the Ca^{2+} current. The inward current in these experiments begins before the voltage has stabilised. Therefore, the early kinetics of activation are obscured. The Ca^{2+} current apparently inactivates.

Inactivation of Ca current

Figures 1 and 3 show that the inward current diminishes in time. Other experiments were done to test whether the Ca^{2+} current inactivates. To obtain a more accurate measure of the Ca^{2+} current from a single cell, a series of experiments was done in which 99% of the $CaCl_2$ in the external solution was replaced by $MgCl_2$. The results of such an experiment are shown in Fig. 4. The records obtained when the cell was bathed in buffer containing 0.01 mM $CaCl_2$ and 0.99 mM $MgCl_2$ resemble those of pawn. They lack the transient inward current but steady-state, outward currents remain unaffected. These results confirm our conclusion that the inward current is a Ca^{2+} current and that this current inactivates.

The effects of Ca^{2+} and Mg^{2+} concentrations on the properties of the membrane were studied systematically. Decrease of external Ca^{2+} lowered the membrane resistance. Increase of external Ca^{2+} increased the resistance and raised the measured activitation potential for the inward current. The measured activation potential for the inward current was also raised when Mg^{2+} was added to the standard 1 mM $CaCl_2$ buffer. These results suggest that surface-potential effects must be considered in studies of *Paramecium*, and that lowering the divalent cation concentration indirectly affects membrane resistance and the channel's apparent activation potential in addition to changing the driving force of Ca^{2+} across the membrane[22].

Acidic phospholipids in the paramecium membrane give the membrane a negative surface charge. This must cause a relatively higher concentration of cations near the membrane than in the bath. Changes in the ion composition of the bath, particularly in its divalent cation concentration, will alter the surface potential and ion concentrations in the vicinity of the membrane, and thus the electric field to which the membrane components are subjected may be quite different from that measured at a distance[23]. The experimental result that neither the measured activation potential for delayed rectification nor the hyperpolarisation currents are affected if Mg^{2+} is substituted for Ca^{2+} suggests that Mg^{2+} does substitute for Ca^{2+} in its effects on membrane resistance and surface potential but that it does not cross the membrane through the Ca channels[23,24].

The rate at which inactivation is removed when the membrane was held at resting potential was studied by stimulations paired at various intervals. A sample trace of such an experiment is shown in Fig. 5. Two depolarising pulses were given, each 5 ms long. An inward current is the response to a first depolarisation but it is lacking after the second. The time course showing the recovery of the inward current is shown in Fig. 5. It takes 80–90 ms for inactivation to be removed after a 5 ms pulse.

Ca-activated K conductance not involved

A Ca-acitvated potassium conductance has been shown to exist in a number of systems[25,26] that possess an inward Ca^{2+} current. It therefore seems possible that the observed loss in time of inward current is not caused by inactivation but by an activation by Ca^{2+} of an outward current which eventually cancels the inward current. The experiment shown in Fig. 6 demonstrates that this is not the case. If we

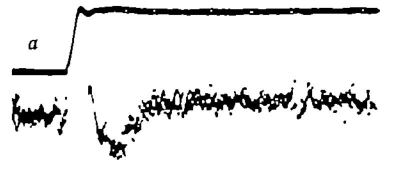

Fig. 4 Separation of currents in a wild-type cell by ion substitution *a*, Current response (noisy trace) to a step depolarisation (smooth trace) in a bath containing 1 mM Ca^{2+}. *b* Current, response to a similar depolarisation in the same wild-type cell when the bath was changed to one with 0 01 mM Ca^{2+} and 0.99 mM Mg^{2+}. The transient inward current seen in the upper trace is not seen when the external Ca^{2+} concentration is reduced but steady-state currents are equal This effect is reversible. Due to use of microelectrodes with relatively high resistances, unavoidable when voltage-clamping *P. tetraurelia*, a current oscillation follows the capacitative current at the beginning of the step depolarisation The membrane potential first was held at the resting potential, −25 mV, then depolarised to − 10mV in each case. Calibration bars· 20 mV, 10 nA and 4 ms. Each record shows four superimposed traces.

suppose that in the steady state there is a Ca-activated K^+ current component which cancels some of the inward current, then a sudden change of potential to more negative than E_K (ref. 21) ($E_K = -38$ mV in *P. tetraurelia*, unpublished observation) would reverse the direction of the K^+ current while the Ca^{2+} current should remain inward. Thus, the Ca^{2+} current and the hypothetical K^+ current which are supposed to cancel at -10 mV should add at a membrane potential below -38 mV. But, the observed hyperpolarising current is the same, with depolarising prepulse and without. There is, therefore, no measurable, long-lasting, Ca-activated K^+ current in the steady state which could be considered responsible for cancelling of an inward current. Ca-activated K channels may well exist in the *Paramecium* membrane (Y. Satow and C. Kung, in preparation). But, these channels seem not to be activated at internal Ca^{2+} concentrations or with kinetics relevant to excitation, in the conditions described in this paper. The relatively slow increase of the inward current during hyperpolarisation is due to activation of a different K conductance which causes an anomalous rectification (Oertel *et al.*, unpublished and ref. 27).

Concentration and conductance of Ca^{2+} per cilium

Two independent studies have shown that the excitation-related Ca channels are located mostly, and perhaps exclusively, in the cilia[28,29]. Thus it is likely that it is the local concentration of Ca^{2+} in the cilia, and not the concentration in the general cytoplasm, which controls beat direction. An order-of-magnitude estimate can be made of the increase in Ca^{2+} concentration in a cilium during an action potential. For this rough estimate we make the simplifying assumption that the time course of the Ca^{2+} current during an action potential is similar to that measured in voltage clamp conditions. Such an assumption seems reasonable, because the action potentials last so long that almost all channels should be open and inactivated[3,4]. 8×10^{-17} equivalents of Ca^{2+} are transferred during a 20 mV depolarising pulse. Taking the collective volume of all cilia of one cell to be 1.7×10^{-12} l, the change in Ca concentration in cilia would be about 2.3×10^{-5} M.

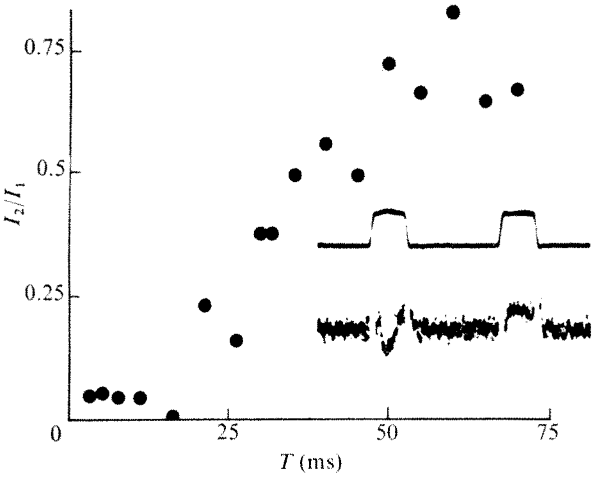

Fig. 5 Time course of return to resting state after inactivation in wild-type paramecium. Two 5-ms depolarisations each of 15 mV were given at various intervals. The ratio of the magnitudes of the second inward current to the first (leakage current subtracted) plotted as a function of time between end of first and second voltage pulse. Inactivation, nearly complete for about 20 ms, was removed after about 80–90 ms. Cell held at -18 mV between pulses. Sample trace is from a different cell with lower resting potential, but shows results more clearly because of smaller current swings after voltage changes.

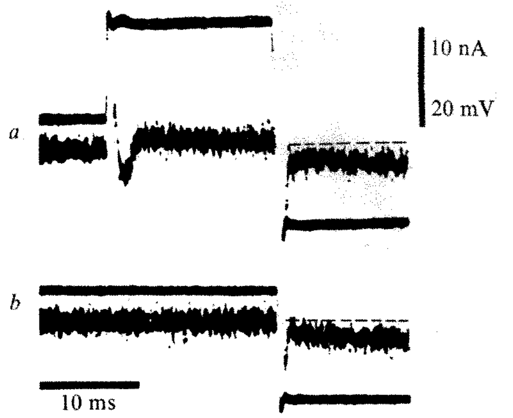

Fig. 6 Transience of inward Ca^{2+} current is not due to slow increase of a masking rectifying current but to an actual decrease of Ca^{2+} current (inactivation). *a*, Current response (noisy trace) to a step depolarisation followed by a hyperpolarisation (smooth trace). *b*, Current response of hyperpolarisation only without a depolarising prepulse. To detect hypothetical currents, assumed to cancel during depolarisation, current responses to hyperpolarisation are compared in *a* and *b*. If transcience of the inward current, seen when the cell is depolarised, is due to Ca^{2+} inactivation, the steadystate current should comprise only small rectifying and leakage currents. Hyperpolarisation to a potential (-48 mV) more negative than E_K (-38 mV) must reverse any postulated rectifying currents making all ion currents inward and additive. The observed current following depolarisation in *a*, however, is not detectably larger than in (*b*). Therefore, the inactivation, lasting for 80–90 ms, cannot be explained by postulated long-lasting rectifying currents.

Using paramecia whose membranes were made leaky with a detergent, Naitoh and Kaneko[16] showed that 10^{-6} M Ca is the threshold for ciliary reversal. Our estimate indicates that each action potential can deliver enough Ca^{2+} to cause ciliary reversal. Eckert[30] arrived at a similar conclusion by calculating how much Ca^{2+} was needed to charge the membrane capacitance.

It is also possible to make a rough estimate of the Ca^{2+} conductance per cilium. The maximum Ca^{2+} current measured is 4 nA for a depolarisation to 0 mV. If one assumes that the equilibrium potential for Ca^{2+} is about 150 mV, the maximum conductance per cell is 27 nmho, a value in close agreement with that calculated by Schein *et al.*[9], and the maximum conductance per cilium is only 5 pS.

Discussion

Indirect evidence further supports our finding that Ca channels in *Paramecium* inactivate. Naitoh and Eckert[3] and Naitoh, Eckert and Friedman[5] showed that the action potential of *Paramecium* is refractory. Since it also shows no undershoot which would indicate a maintained increased permeability to K^+, the refractoriness of the action potentials must be due to Ca inactivation. Eckert, Naitoh and Machemer[2] suggest that the *Paramecium* Ca current is at least partly transient. They found that small depolarising voltage-clamp pulses of several seconds produce only transitory reversals and that large and long depolarising pulses produce ciliary reversals which decrease in frequency with time. The transitory reversals observed by these authors last much longer than our calculated Ca^{2+} current. It is, however, difficult to compare time courses of currents and with those of ciliary reversal because little is known about how internal Ca concentration is regulated. Ultimately, it is internal Ca^{2+} concentration, not Ca current, which regulates reversal[2,16,31].

The Ca^{2+} action potential in *Paramecium* resembles Ca^{2+} spikes in metazoan systems[13,14,32–34]. In all cases, the action potentials are graded; Ba^{2+} and TEA^+, applied externally, change the action potential from graded to all-or-none[32,33].

But it is not possible to make generalisations about inactivation. Hagiwara[32] and Keynes *et al.*[13], for instance, report that the Ca^{2+} current in barnacle muscle does not inactivate, whereas Mounier and Vassort[32] show that the Ca^{2+} current in crab muscle does inactivate.

We have shown that the *pwB* mutation of *Paramecium tetraurelia* eliminates the transient inward Ca^{2+} current that occurs in the wild type on depolarisation. This observation enables us to separate the Ca^{2+} inward current, much as one uses tetrodotoxin to separate the Na^+ current in nerve cells, from the leakage and rectifying currents.

letters to nature

Airborne studies of thunderstorm electrification

THERE is considerable controversy[1,2] surrounding the problem of thunderstorm electrification. Many scientists have maintained that precipitation acquires substantial charges and that field growth to breakdown magnitudes is a consequence of the separation under gravity of the precipitation and the oppositely charged cloud particles. Others have argued that precipitation is incidental to field growth, and have reported lightning from clouds in which the precipitation rates are very low. Of the charging mechanisms involving precipitation, the inductive mechanism[3,4] has been generally favoured. Under this mechanism rebounding collisions of small cloud particles with the underside of precipitation elements result in the removal from the latter of polarisation charge, and the maximum charge Q_m (pC) that can be acquired by an element of diameter d (mm) in a field E (kV cm^{-1}) is given by

$$Q_m = 5.5Ed^2 \qquad (1)$$

We summarise here the results of some airborne experiments conducted in the summer of 1976 in Florida, as part of the Thunderstorm Research International Programme, and subsequently in Socorro, New Mexico. The major objectives of this study were to determine whether substantial currents are carried on precipitation in thunderclouds, and to investigate the relationship between Q, E and d for precipitation particles—and thereby to test the applicability of equation (1) to thunderstorm electrification.

The measuring equipment was carried on the ONR/NMIMT Schweitzer aircraft. This was originally a drone, but it has been modified to accommodate a pilot. Its particular virtue—which renders it excellent for these experiments—is that it flies very slowly (around 40 m s^{-1}). Thus it has a minimal effect on any clouds through which it passes. Its ceiling altitude is 13 km.

The electric field in three mutually perpendicular directions was measured using five appropriately sited field mills. Simultaneous measurements of the charge and size of precipitation particles were made with a novel device mounted under one wing of the aircraft. An aluminium cylinder of length 80 mm and diameter 50 mm was mounted with its axis parallel to the airflow. The charge Q carried on a hydrometeor which passed through the device without touching it was sensed by induction and measured using a charge amplifier. A major problem with such a method is that spurious signals may arise from collisions of hydrometeors with the sensing cylinder. This was circumvented by making the time constant for decay of charge (resulting from such a collision) about 10 times longer than the transit time (and thus the duration of the charge-pulse) associated with the clean passage of a hydrometeor through the cylinder. The two types of pulse could be distinguished unequivocally and only the true ones (clean passages) were accepted. Various practical tests demonstrated that the sensitivity of the charge amplifier was consistent with that derived from an analysis of the circuit. The device was so arranged that it was impossible for hydrometeors to splash into the induction cylinder from any part of the aeroplane. Insulation loss in the charge amplifier—which happened occasionally in very heavy rain—was easily recognised from the recorded signals. Values of Q up to ±150 pC could be measured to an accuracy of ±5 pC.

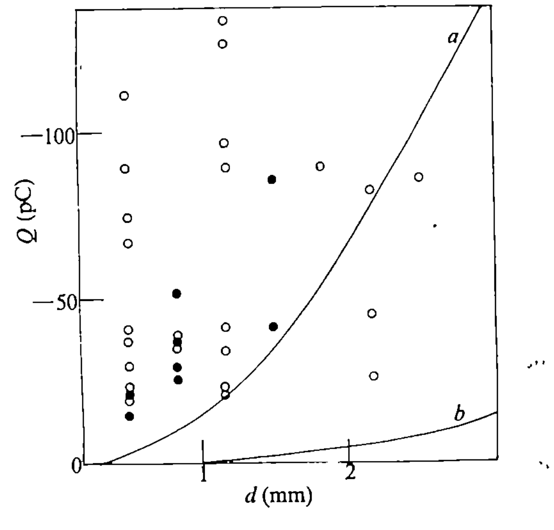
The coincident measurements of the size d of hydrometeors passing through the induction cylinder were effected by means of a shadowgraph technique. A beam of light passed across the cylinder, perpendicular to its axis, and half way along its length. It illuminated a linear array of 64 photo-diodes, spaced 100 μm apart, their line being perpendicular to the axis. When a particle passed cleanly through the beam illumination of some of the diodes was obscured and an electrical pulse was obtained whose magnitude was related in a known way to the size d of the particle. A flagging arrangement permitted the rejection of signals associated with particles which passed through the edge of the beam. A series of calibration experiments, employing stationary wires and also pellets of known size fired from a gun through the light beam illuminating the diode array showed that the values of d were accurate to ±0.3 mm. The range of values of d that could be measured was 0.5 to 4.4 mm. The device is uncomplicated, functioned consistently well and (by integration of the *d*-pulses) provided crude but sensible estimates of precipitation rates. The tape-recorded commentary of the pilot showed that his observations of the presence or absence of raindrops coincided accurately with the information given by the device.

There was no difficulty in identifying *Q*/*d* coincidences from our tape-recorded charge and size pulses. The spacing in time of coincident *Q*/*d* pulses was typically one or two orders of magnitude shorter than the mean intervals between successive *Q* or *d* pulses. The measurements of electric field, particle size and particle charge were telemetered to ground, as was the pilot's commentary (which was very important in these studies) and other measurements. In 1976 much of the effort was devoted to optimisation of the various instruments carried on the Schweitzer, and most of the measurements were devoted to horizontal penetrations near the bases of thunderclouds, where the vertical field was generally negative (that is, in opposition to the fine weather field).

The great majority of precipitation particles were found to carry negative charges. Over extensive horizontal distances, with vertical fields up to about -30 kV m^{-1}, the volume charge density on precipitation ρp—obtained by summation of the individual charge pulses—was in the region of -5 nC m^{-3}. The corresponding precipitation current j was around 15 nA m^{-2}. These values of ρp and j are of sufficient magnitude[5] and of the correct sign, to generate breakdown fields in the central regions of thunderclouds in the time generally considered to be available.

The number of coincident measurements of *d* and *Q* was limited because only about 20% of the particles entering the cylinder would pass through the light beam, and some insulation problems with the *Q* device were experienced in heavy rain. The coincidences obtained for two particular penetrations are displayed in Fig. 1. They show that no simple relationship exists between *Q* and *d*. Furthermore, the charges carried on the precipitation are usually far greater than the maximum (curve *a*) that they could acquire under an inductive mechanism operating even in regions where the field was at breakdown value. The charges on some of the smaller particles were close to the Rayleigh bursting limit and many of these hydrometeors carried charges in excess of those which would be required for levitation in positive fields of breakdown magnitudes.

Fig. 1 Measured coincident values of charge *Q* and size *d* of precipitation elements during two penetrations on 9 August 1976. ○, Penetration 3; ●, penetration 4. Curve *a* from equation (1) with $E = 300$ kV m^{-1} Curve *b* from equation (1) with $E = 21$ kV m^{-1}, which was characteristic of the field values measured during these penetrations.



It was not possible to make precise estimates of precipitation rate p from the *d*-pulses, because the sampling volume was small. It was established, however, that in regions where the values of ρp and j were large p did not generally exceed about 10 mm h^{-1}; and on several occasions appreciable values of ρp were measured when p was below 1 mm h^{-1}. These observations of low precipitation rate were confirmed by the visual observations of the pilot.

Records from flights made on several days confirm our general findings—that precipitation currents and charge densities can be very high, even when precipitation rates are low, and that the individual values of *Q* are inexplicable in terms of the inductive theory. Thus it appears that precipitation may well play a major role in thunderstorm electrification, but that the mechanism responsible for the charge transfer remains to be identified.

A full discussion of these experiments will be described in a lengthy paper, currently in preparation.

We are indebted to Mr J. W. Bullock, the pilot of the aeroplane. Mr R. Binford, Mr S. Hunyady and Mr A. Pennington made substantial contributions to this work. Pattern recognition applied to uranium prospecting

PATTERN recognition techniques provide one way of uniting quantitative and descriptive geologic data for mineral prospecting. A quantified decision process using computer-selected patterns of geologic data has the potential of selecting areas with undiscovered deposits of uranium or other minerals. When a natural resource is mined more rapidly than it is discovered, its continued production becomes increasingly difficult. For example, Lieberman[1] has noted that, although a considerable uranium reserve may remain in the U.S.A., the discovery rate for uranium is decreasing exponentially with cumulative exploration footage drilled. Pattern recognition methods of organising geologic information for prospecting may provide new predictive power as well as insight into the occurrence of uranium ore deposits. Often the task of prospecting consists of three stages of information processing: (1) collection of data on known ore deposits; (2) noting any regularities common to the known examples of an ore; (3) selection of new exploration targets based on the results of the second stage. Here we describe a logical pattern recognition algorithm that implements this geologic procedure to demonstrate the possibility of building a quantified uranium prospecting guide from diverse geologic data.

We chose to test prospecting by pattern recognition in an area with dimensions 85 × 90 km of the Colorado–Utah border between 108°30′W to 109°30′W and 38°0′N to 38°45′N. This area contains many commercial uranium deposits as well as much unproductive area[2]. Because this part of the Colorado Plateau is relatively well understood and explored, pattern recognition classification of barren and uranium-bearing areas may be verified by comparison with the results of past field exploration and development.

In the study area, uranium deposits occur chiefly as pene-concordant ore bodies in the Jurassic Morrison formation, a continental sandstone interbedded with mudstone. Most geologists agree with Hostetler and Garrels[3] that the deposits were formed when uranium minerals precipitated from groundwater flowing through gently dipping sandstone beds with locally strong reducing capacity. Fossil plants and humic material seem the most likely sources of reducing agents. Uranium may have been derived from distant upland rocks, basement rock, overlaying beds containing volcanic ash, updip leaching of the host formation, or hydrothermal circulation associated with intrusives.

The principal recognition algorithm used here has been described in full elsewhere[4,5]. In the present experiments, a computer searches geologic data for discriminants (called traits) that can be used to classify locations as either uranium-bearing or barren. In a training stage, the locations of known uranium deposits are presented to the computer together with geologic data at a number of sites in a study area. In the training district, the goal of data analysis is the identification of a set of geologic traits that discriminate producing areas from barren sites. This set of traits may then be taken to unexplored areas and used to predict the location of uranium-prone sites. Perfect classification, even of locations in a training district, is not expected because adequate geologic data may not be available, all ore bodies in a district may not have evolved similarly, some undiscovered ores may be incorrectly designated as barren, and instructions to the computer may not be optimal.

Many types of data, from standard geologic maps, geophysical, geochemical, and radiometric surveys and satellite imagery are now used in commercial exploration for uranium. In the present study, only readily available structural, stratigraphic, and geomorphic information was used in computerised prospecting. This information does not include many significant geologic features of uranium-bearing areas. Because major pre-ore structural features may have strongly influenced the flow of uranium-bearing groundwaters, however, this simple geomorphic information should have a considerable role in ore body location and will demonstrate the potential of pattern recognition techniques in prospecting.

Before analysing geologic data for patterns, several individual geologic features are tested to find some that are particularly characteristic of producing or of barren areas. The selection of features for recognition is based on estimates obtained from the training district of state-conditional probability density functions for the occurrence of features. Geologic data are simplified to binary-valued features, and a string of binary digits is used to describe each location (examples of the data available for this study are given in Table 1). The computer then uses this data base of binary features to contrast barren and producing areas by constructing more complex logical descriptions of these two classes of locations from the binary feature primitives. In this way, the computer may reveal logical relations particularly useful in uranium prospecting within large quantities of diverse geologic data.

Combinations of one, two and three binary values of features taken together constitutes traits. With N binary features

$$2N+4C_N^2+8C_N^3$$

traits are examined, where C_N^M is the number of combinations of N things taken M at a time. With the 19 features of Table 1, for example, no geologist could hope to examine all of the 8,474 possible traits. A computer is used to examine all these and to select the few traits most characteristic of barren and of producing areas. A trait characteristic of producing areas is selected if a trait occurs at more than K_1 producing locations and fewer than K_1* barren locations; similarly, K_2 and K_2* define characteristic traits of barren areas. In the present experiments, K_1, K_1*, K_2, and K_2* were about 60%, 10%, 40%, and 10% of producing and barren areas, respectively. In a final classification stage, if the number of producing traits exceeds the number of barren traits present at a point, the point is classified as uranium-bearing by the computer, otherwise it is classified as barren.

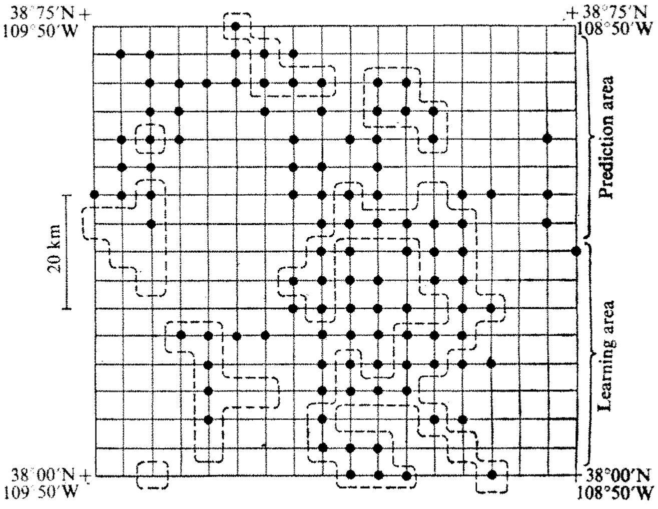
Table 1 Examples of features for recognition of uranium deposits

Position of location between nearest surrounding drainage divides
Lowest elevation within 3 km
Highest elevation within 3 km
Topographic gradient
Average elevation
Maximum bed dip within 5 km
Distance to Quaternary Sediment
Distance to major river
Distance to syncline axis
Distance to NE-trending basement fault
Distance to basement fault intersection
Distance to exposed crystalline rock
Number of formations outcrop within 2.5 km
Distance to anticline
Distance to Cretaceous intrusion
Is nearest anticline closer than nearest syncline?
Convergence or divergence of bed dip over Morrison formation
Does Morrison outcrop in 2.5 km?
Structure contour on Dakota sandstone base

We tested how well the computer can learn in one region and predict in another in a simulated exploration survey. The computer was given geologic data and the locations of known mines in the southern part of our grid. After surveying possible features and developing traits on 162 points in the southern part of our grid, geologic data for 144 points in the northern part of the grid were given to the computer with instructions to select the most likely uranium prospects based on results of learning in the south. Results of this recognition and prediction are given in Fig. 1.

In the training area, 80% of producing points and 82% of barren points were correctly recognised. Most misclassified barren points are adjacent to known deposits, so that these

Fig. 1 Results from Experiment 1. The computer was trained on the southern part of the grid and predicted in the north. Grid points classified uranium-bearing on the basis of traits are indicated by ●. Grid points with known uranium production are within the dashed contour (production data from Williams, 1964).



errors are not unreasonable. With a 5-km grid spacing, some errors are expected as adjacent grid points may have similar descriptions in our limited feature space.

In the north, despite the small training sample and the limited information available in features, the computer did pick as good prospects some points in each of five producing zones. Correct recognition rates in the north are comparable with those in the south, 83% for producing areas and 74% for barren areas. Since no set of locations will resemble the training set as much as the training set itself, an error rate in prediction comparable with that in learning may be regarded as excellent performance. Also, some of the errors in classifying barren points may represent undiscovered deposits.

To further test the method, training and prediction was carried out for the entire area of Fig. 1. This differs from the procedure of learning in one area and predicting in another, and suggests using pattern recognition to identify overlooked deposits within a mining district. Results comparable with those from our Experiment 1 were obtained, attesting to the stability of the method against large variations in the amount of learning material. We gain additional confidence in computerised trait selection because traits are always geologically reasonable, though it is not obvious before applying our procedure which features will be combined into traits for optimum recognition.

To demonstrate that the geologic patterns found by our procedures are not random accidents, control experiments to test for self-deception were performed. Although not a part of standard pattern recognition procedures, some such test is important when considering complex geologic systems. The computer was given spurious but realistic geologic information by holding geologic data at each grid point fixed but rotating the spatial classification pattern to be duplicated by 180°. This rotated pattern retains the spatial distribution and degree of order of the original classification. In this experiment, all 306 grid points were again used as a training set. No traits were found to satisfy the K/K^* conditions imposed on traits from real data. Relaxing the K/K^* conditions to obtain traits, the algorithm could force this artificial data barely above the 50% correct recognition rate expected from random binary selection of prospects. The failure of recognition based on spurious but spatially realistic information (as well as similar failures of recognition based on randomly generated binary features) lends confidence to results based on real data.

In these and related experiments, a contextual/decision theoretic pattern recognition procedure was able to extract significant logical relationships between diverse types of geologic data and to use these relationships in correct recognition of uranium-producing areas. Correct recognition rates up to 85% for uranium-producing areas with few false positives indicates the potential of pattern recognition in selecting exploration targets. When comprehensive data from standard geologic maps, LANDSAT imagery, geochemical, radiometric, and geophysical surveys are available, computerised prospecting procedures may provide a powerful new approach to predicting new areas of commercial resource potential. A complete description of this work will be published elsewhere.

An important ground surface sink for atmospheric nitrous oxide

ONE of the more remarkable achievements of atmospheric chemistry is the identification by Crutzen[1], in 1970, of nitric oxide (NO) as the main natural agent for the destruction of ozone produced photochemically in the stratosphere. The principal source of stratospheric NO is the reaction of excited oxygen atoms (O^1D) with nitrous oxide (N_2O)[2], present as a normal constituent of the Earth's atmosphere. N_2O was first observed, in 1938, by Adel[3] in the absorption bands in the 7.8 μm region of the solar spectrum, but knowledge of its atmospheric life cycle is still very incomplete because of the few measurements available of its atmospheric concentration and limited information on atmospheric sources and sinks. The soil has been suggested as a major source of atmospheric N_2O[4] and the ocean has been proposed to act both as a source[5] and as a sink[6]. The only sink so far positively established by atmospheric measurement lies in the stratosphere, being predominantly photodissociative in nature with an additional contribution from the chemical reaction with excited oxygen atoms[4,7]. We report here evidence for the existence of an appreciable, but unidentified, ground surface sink mechanism.

Interest in monitoring atmospheric N_2O has been stimulated recently, both from realisation of its important role in ozone chemistry, and concern that perturbation of the ozone level in the stratosphere may occur due to enhanced N_2O emissions from the soil arising from increasing world-wide application of nitrogenous fertilisers. McElroy[6] has predicted that a 20% reduction in the concentration of stratospheric ozone may occur by the first quarter of the twenty-first century if present trends in the use of nitrogenous fertiliser continue.

The recent development[8] of the heated electron capture detector for gas chromatographic determination of N_2O has facilitated the measurement of ambient levels of N_2O in air without the need for previous concentration of the air sample[9,10].

In the following, we describe some measurements of N_2O made using such a detector at AERE Harwell in July and August 1976. Outside air was sampled at 5 m above ground level and drawn through a 6 feet stainless steel tube into a 5 cm^3 sample loop. The air in this loop was injected every 2 h into a PYE 104 gas chromatograph equipped with an electron capture detector operating at 350 °C. A 9 feet Porapak QS column, maintained at 27 °C, was used to separate N_2O using a 90% Ar–10% CH_4 mixture as carrier gas flowing at 30 $cm^3\ min^{-1}$. The apparatus was operated continuously for a five-week period commencing 7 July and ending on 9 August; our data was obtained in a period of extremely stable operation from 24 July to 8 August. This was demonstrated both by negligible changes in observed standing current of the detector ($1.00 \pm 0.03 \times 10^{-9}$ A) and by minimal changes in the signal displayed by injecting a standard sample at regular intervals. (0.278 ± 0.005 p.p.m.). During the same period outside air samples gave values ranging from 0.233 to 0.315 p.p.m.

The most important aspect of the data, shown in Fig. 1, is the observation of a regular diurnal variation of N_2O concentration on each of the 11 days shown. A minimum was nearly always recorded in the early hours of the morning and a maximum was recorded in the late afternoon or evening. Since the amplitude of this diurnal variation was only about 10% of the mean value, we have taken particular care to establish that it was not due to diurnal changes in instrument sensitivity associated either with changes in instrument conditions such as ambient temperature, or with changes in the concentrations of other atmospheric species such as water vapour or carbon dioxide. The observations, therefore, seem to indicate a real physical phenomenon which can only be explained either by some process which increases the N_2O concentration during the day, or alternatively depletes the N_2O concentration at night. Pierotti and Rasmussen[11] have noted that the N_2O concentration

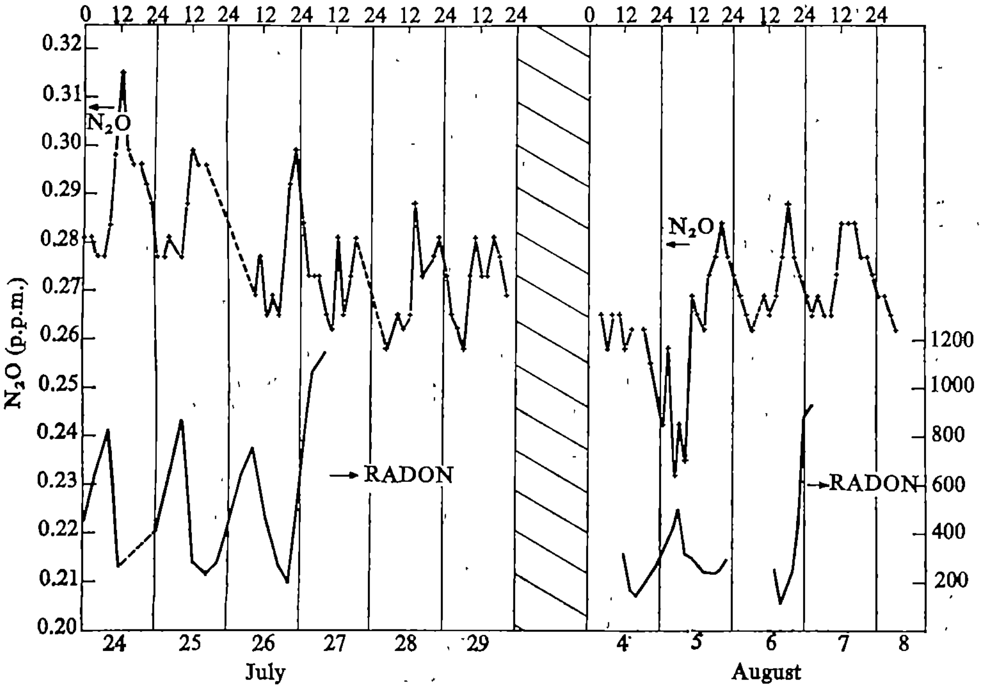

Fig. 1 Daily variation of N_2O and radon from 24 July to 29 July 1976, and from 4 August to 8 August 1976 (– – –, data pattern uncertain).

in power plant plumes is increased above the background level, but there is no reason why such combustion processes should lead to regular increases of the type shown in Fig. 1.

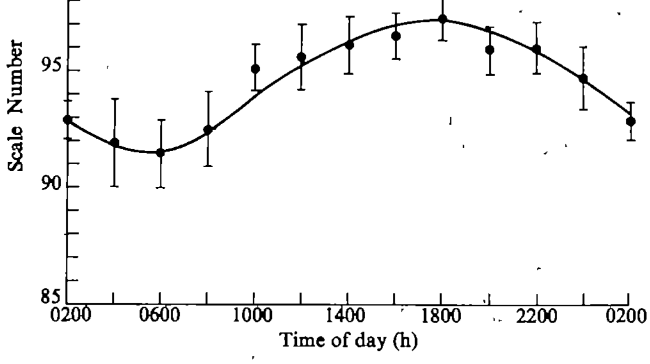
It seems rather that N_2O exhibited diurnal behaviour typical of gases such as sulphur dioxide, ozone and peroxyacetyl nitrate (PAN) which are absorbed at ground level surfaces[12,13]. Measurements of such gases made near the ground show a reduction in concentration at night, as they become depleted in the shallow layer of stable air which develops below the nocturnal inversion, and a rise during the day, as solar radiation gradually breaks up the inversion and allows fresh material to mix downwards. Inversions developed on many nights during the observational period which was characterised by anticyclonic weather conditions and clear skies.

Such diurnal behaviour is anti-correlated with that of radon[14] which is emitted rather than absorbed, at the ground surface. Included in Fig. 1 are the atmospheric radon concentrations, also measured at Harwell with continuous monitoring equipment, which showed this strong anti-correlation with the N_2O observations on several days during the period. A possible alternative explanation would be a gas-phase reaction with another gas released at ground level, but this is unlikely with a gas as unreactive as N_2O and no suitable candidate reactions have been suggested in the literature. Thus we conclude that absorption of nitrous oxide, probably by vegetation or the soil, is the most likely explanation of our observations though the mechanism by which this occurs is not clear.

Matsubara and Mori[15] suggested that N_2O would be removed by soil microorganisms and some recent investigations by Blackmer and Bremner[16] provides experimental evidence that soils can possess more potential to act as a sink than as a source of N_2O in conditions favourable to denitrification. These observations indicate that a sink other than destruction in the stratosphere may be significant for atmospheric N_2O. If the deposition is occurring irreversibly then the size of this sink can be estimated from the deposition velocity (v_g), which is related to the exponential decay constant λ, governing the rate of concentration decrease by the simple expression $\lambda = v_g/h$ where h is the height of the stable layer from which deposition is occuring[12,17].

Figure 2 illustrates the average diurnal pattern for the period in question. This was derived by assigning a value of 100 to the maximum N_2O concentration observed during any 0000–2400 cycle and scaling the other measurements accordingly. For the days considered, the scale numbers were then averaged for each respective sampling time. The average value of λ for decay of N_2O between 1800 h and 0600 h can be derived from Fig. 2, using a value of 0.280 p.p.m. for the mean N_2O concentration during the period. The magnitude of h is unknown, but, since it is the same for all gases undergoing deposition, the v_g for N_2O can be obtained directly by comparison with data on the average diurnal variation of ozone at Harwell over the same period. The value of λ for N_2O from Fig. 2 is $(5 \pm 0.7) \times 10^{-3}$ h^{-1} and the corresponding λ for ozone is (0.12 ± 0.02) h^{-1}. Since the average deposition velocity for ozone observed in similar conditions is about 0.3 cm s^{-1} [18] we calculate a value for N_2O of 1.25×10^{-2} cm s^{-1}. If, in the absence of further information, we assume this value is typical of all land surfaces then we can estimate the magnitude of the global sink for N_2O. The mean atmospheric lifetime of a species being removed by deposition at the Earth's surface is equal to H/v_g, where H is the equivalent height of the atmosphere (8.3 km) and v_g is the mean deposition velocity for the earth's surface. Assuming that deposition occurs all year at the same rate but only on land surfaces (0.26 of the total surface) then the life time of N_2O due to this sink is 8.1 yr. Taking a mean mixing ratio for N_2O of 0.3 p.p.m.[19],

Fig. 2 Average diurnal variation for N_2O. ⊕, Average scaled number value for corresponding injection time; I, ±1 standard error of the mean.



the magnitude of this sink is estimated at 320 Mt yr^{-1}. This figure, which can only be very approximate at this stage, is twice the surrent estimated combined ocean source, 135 Mt yr^{-1} [5], and soil source, 25 Mt yr^{-1} [4]. It is more than an order of magnitude greater than the figure of 13 Mt yr^{-1} for the stratospheric sink[20]. Use of the mean lifetime figure of 8.1 yr would substantially reduce McElroy's estimate of the reduction in stratospheric ozone due to the use of nitrogenous fertilisers.

Further data in a variety of conditions are needed before the global magnitude of this sink mechanism, which seems larger than any other, can be estimated with confidence.

This work was carried out as part of the Atmospheric Pollution Project at Harwell supported by the Department of the Environment. Our thanks are due to R. G. Derwent for provision of ozone and radon data and to him and J. A. Garland for helpful discussions.

Generation of a supported iridium catalyst of extremely high dispersion

THE preparation of supported metallic catalysts in a very high state of dispersion—that is, with a very small average metallic particle size—is of considerable current interest. Not only is the surface area per unit mass of metal thus increased, but if the metallic particles are sufficiently small, their intrinsic catalytic properties may be different from those of the massive metal. On the whole, changes of the latter sort seem to be found when the particle diameter is less than about 2 nm (refs 1, 2). The use of a metallic cluster carbonyl (MCC) as a means of preparing a dispersed metallic catalyst has been the subject of preliminary exploration[3,4,5]. Although it was indicated that this route could yield highly dispersed metal, it was clear[3] that considerable cluster aggregation occurred during thermal decarbonylation and hydrogen reduction (at 573 K). This note reports the preparation from $Ir_4(CO)_{12}$ of a supported iridium catalyst in a very high state of dispersion.

The preparative details are: the support (Wohlm γ-alumina, 200 m^2 g^{-1}) vacuum-dried at 380 K for 15 h, was impregnated using the method of incipient wetness with a solution of $Ir_4(CO)_{12}$ used as obtained from Alpha Chemical Inc in cyclohexane (0.4 mg cm^{-3}, AR grade saturated). After standing for a few hours, the solvent was removed under vacuum at room temperature, and the sample was then heated to 623 K under vacuum for 4 h. The sample was then heated in hydrogen at 623 K for 15 h, and was then evacuated to better than 1 mPa at the same temperature. At this point, the catalyst was ready for characterisation by gas adsorption (H_2 or CO) or by electron microscopy. Catalyst compositions were determined by X-ray fluorescence.

The results for catalyst samples with loadings of 0.31 and 2.48 wt % iridium (dry weight basis) are given in Table 1. The extent of gas uptake over the pressure range 0.3–3 kPa was virtually independent of pressure and is taken to correspond to monolayer adsorption. In the case of iridium it is reasonable to take the monolayer chemisorption stoichiometry for hydrogen, $X_m(H_2) = 2$ (1), that is each surface iridium atom carries one hydrogen atom at monolayer coverage. On this basis the average iridium particle diameters were computed which are also included in Table 1 for comparison with the electron miscroscopic data.

Table 1 Characterisation of supported iridium catalysts

	Gas adsorption, ‡ 293 K 0.3–3 kPa (10^{21} molecules per g Ir)		$N_{(s)H}/N_{(T)Ir}$†	$N_{(s)CO}/N_{(T)Ir}$†
	H_2	CO		
$Ir/\gamma\text{-}A1_2O_3$ 2.48 wt % Ir	0.67	1.45	0.43 (2.5 nm)*	0.46
$Ir/\gamma\text{-}A1_2O_3$ 0.31 wt % Ir	1.51	7.66	1.0 (<1.1 nm)*	2.44

* Average iridium particle diameter obtained from $N_{(s)H}/N_{(T)Ir}$ and $X_m(H_2) = 2$.

† Obtained using the result that 1 g Ir contains 3.13×10^{21} atoms: $N_{(s)}$ and $N_{(T)}$ number of atoms at surface and in total respectively.

‡ Corrected for adsorption on the support.

Two main conclusions emerge from Table 1. For the catalyst for which $N_{(s)H}/N_{(T)Ir}$ (which equals the metallic dispersion $D = N_{(s)Ir}/N_{(T)Ir}$ by virtue of the value assigned to $X_m(H_2)$) is less than unity, there is reasonable agreement between $N_{(s)H}/N_{(T)Ir}$ and $N_{(s)CO}/N_{(T)Ir}$ at monolayer coverage, indicating $X_m(CO) \simeq 1$. However, in the case of the catalyst with the lower iridium loading of 0.31 wt % Ir for which $N_{(s)H}/N_{(T)Ir} = 1$, the value of $N_{(s)CO}/N_{(T)Ir}$ indicates $X_m(CO) = 2.44$. Although it is known that for extremely highly dispersed platinum the monolayer chemisorption stoichiometry ($X_m(H_2)$) may fall somewhat below two[2], we have not observed similar behaviour with extremely highly dispersed iridium. Bearing in mind that $D = 1.0$ is consistent with a range of particle sizes below a limit of about 1.1 nm in the case of iridium, and also noting that for this catalyst we failed to resolve any metallic particles electron microscopically, it is clear that the average iridium particle size was extremely small, certainly <1 nm. Since one would expect a range of particle sizes, it is reasonable to expect that some proportion of the iridium was retained as Ir_4 clusters. It remains to be assessed whether $N_{(s)CO}/N_{(T)Ir} = 2.44$ indicates that this proportion was substantial. Comparison with some results of Della Betta[6] for highly dispersed ruthenium catalysts suggest that the answer is probably in the negative. Della Betta studied the adsorption of H_2 and CO for average Ru particle sizes in the range 1.1–2.5 nm (evaluated from H_2 chemisorption data, and assuming $X_m(H_2) = 2$); the corresponding values for $N_{(s)CO}/N_{(T)Ru}$ were in the range 2.3–3.8. Clearly, with a metal for which a molecular cluster carbonyl exists ($Ru_3(CO)_{12}$ in the case of Ru), $N_{(s)CO}/N_{(T)M}$ can approach a value characteristic of the MCC even though the metallic particle size may be rather larger than that existing in the MCC itself.

Comparison with the results of Smith *et al.*[4] suggests that unaggregated metallic cluster skeletal units generated from metallic cluster carbonyls, cannot be retained on these supports if the temperature rises substantially above room temperature. This is probably a consequence of the facile migration of these units across these support surfaces at elevated temperatures. It may prove possible to overcome this problem by designing supports with surface sites of high binding energy at which the metallic cluster skeletal units may be immobilised, or to restrict skeletal unit migration by controlled pore structure of the support. These approaches are currently under investigation.

The authors thank Dr J. V. Sanders for help with the electron microscopy.

Hydrogen in the Earth's core

THE density of the Earth's core is 8–10% less than that of pure iron at the same pressure and temperature[1] and this is usually interpreted as implying the existence of a substantial amount of light element(s) in the core. Many possibilities have been considered[1], with sulphur and oxygen[2] receiving most recent attention, but in this note the discussion is limited to hydrogen's contribution to the density deficit. It is shown that hydrogen is not only effective in decreasing the density but is also highly soluble in iron in the relevant conditions. Only about 1% by mass of hydrogen is required in the Earth's core to explain the density deficit, and this corresponds to a hydrogen–iron mass ratio that is only about one-tenth of that present in type I carbonaceous chondrites[3]. The significance of hydrogen as a contributor to the density deficit is, therefore, determined by the extent to which the Earth-forming matter consisted of low temperature condensates.

Hydrogen was prominent in the earliest discussions of core composition[4,5] but since it enters iron as interstitial atoms, Ringwood[6] proposed that it could not significantly contribute to the density deficit. In fact, the interstitial hydrogen substantially expands the host metal, and the zero pressure hydrides of transition metals are typically 10–20% less dense than the pure metal[7], in contrast to ionic or covalent hydrides. This has frequently been interpreted as the formation of the large (but highly compressible) H^- ion[7], but the thermodynamics are better understood in terms of a screened proton model[8], according to which the hydride can be thought of as an alloy of the transition metal and metallic hydrogen.

For simplicity, consider a host metal characterised by rigid ion cores of size r_c and effective charge Z (not necessarily an integer) immersed in an essentially uniform compensating electron gas. The energy per ion of the alloy $M_{1-x}H_x$, where M is the host metal, is then

$$E = (1-x)E_M(V_M)+xE_H(V_H)+\delta E_{MH} \qquad (1)$$

where V_M is the volume occupied by Z conduction electrons, $V_H = V_M/Z$, E_M and E_H are the energies per ion of the pure host metal and pure metallic hydrogen[9] respectively, and δE_{MH} is a small correction term (which includes the M–H interaction). Neglecting δE_{MH}, the small x limit gives

$$x = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial x}\right)_\rho \simeq \frac{P-P_H-B}{ZB} \qquad (2)$$

where ρ is the mass density, P is the pressure, B is the host metal bulk modulus, and P_H is the pressure that metallic hydrogen would have if it had the same conduction electron density as the host metal. At pressures less than a few megabars, $P_H < 0$ and $B \gg P$ or $|P_H|$, so $\alpha \simeq -1/Z$, and the model approximately predicts the observed density decrease.

According to the empty core pseudopotential model[10], the known equation of state for iron[11] is consistent with $Z \simeq 2$ near $P = 0$ and $Z \simeq 3$ at Mbar pressures, both with $r_c \simeq 0.49$ Å. More realistic models for iron yield similar results for α. Since $|\alpha|$ decreases as P increases, the hydride is more compressible than the host metal, but not to such an extent as to be incompatible with the known pressure–density relationship in the Earth's core. An alloy with composition similar to FeH would explain the observed core density. Inclusion of δE_{MH} in the calculation actually decreases the required amount of hydrogen slightly. Thomas–Fermi calculations[12] predict that a much larger amount of hydrogen is needed, essentially because that method overestimates the conduction electron density.

Just above the iron melting point, the hydrogen solubility[8] for $x \ll 1$ is $x \simeq 0.015\ P^{1/2}$, where P is in bars, so a pressure of a few kbar suffices to form an FeH composition. At much higher pressures, where the coexisting molecular hydrogen ceases to be an ideal gas, the hydride should form even at $T = 0$ K, because the enthalpy of molecular hydrogen increases more rapidly than that of metallic hydrogen[9]. In the low temperature limit

$$x \simeq \exp(-\Delta H/k_B T) \qquad (3)$$

where ΔH is the enthalpy of hydride formation per proton and T is the temperature. At $P = 0$, $\Delta H = \Delta H_0 \simeq 0.25$ eV (ref. 8). At $P \neq 0$, equation (1) with $\delta E_{MH} = 0$ implies

$$\Delta H \simeq \Delta H_0 + P\left(V_{el} - V_{H,mol} - \frac{P_H}{B}V_{el}\right) \qquad (4)$$

where V_{el} and $V_{H,mol}$ are the volume per conduction electron in the hydride and volume per proton in the molecular hydrogen phase, respectively. From the known properties of molecular and metallic hydrogen[9], $\Delta H < 0$ if $P > 200$ kbar. Allowances for $\delta E_{MH} \neq 0$ and finite temperature in the Earth's core do not significantly alter this prediction for hydride formation. At pressures much higher than that in the Earth's core, hydrogen may again become insoluble[13].

The proposed hydride would be an excellent conductor, perhaps even better than pure iron (since metallic hydrogen conducts electricity or heat over 10 times better than iron at the same pressure and temperature[14]). It would also have a lower melting point than pure iron, and other properties which are compatible with present knowledge of the Earth's core.

If at least 10% of the Earth-forming material was a low temperature condensate (containing hydrogen in the form of water) as many models require[1,2], then the proposed core composition is possible. The extent to which hydrogen (or water) was lost during the heating accompanying Earth formation depends on the detailed pressure and temperature history. If, for example, the water reacted with iron at a pressure such that most of the released hydrogen could enter in solution with iron, then volatile retention could be high. The decreasing abundance of water with increasing metamorphic grade in chondrites is not an argument against volatile retention, since the hydrogen is only retained at high pressure, and would be expelled if the pressure were subsequently released. In conclusion, hydrogen is conceivably the major cause of the density deficit in the Earth's core, but is most probably just one of several contributing causes.

I thank A. E. Ringwood for useful discussions.

Geochronology of some blueschists from Ile de Groix, France

THE Ile de Groix series consists of metavolcanic and metasedimentary rocks, with or without glaucophane. These rocks belong to a South Brittany polymetamorphic complex which is named the 'domaine de l'Anticlinal de Cornouaille' by Cogné[1]. In this complex, anatectic granites occur in the midst of a migmatitic and gneissic terrain[1,2]. Some metasedimentary and metavolcanic rocks which occur in the terrain are cut by Hercynian granites. The Ile de Groix series[1,3,4] is characterised by high pressure mineral assemblages with glaucophane, jadeitic pyroxene and lawsonite[5]—these assemblages are unknown on the adjacent mainland. The series is considered to have formed during two metamorphic periods: the first produced high pressure–low temperature mineral assemblages and the second produced a recrystallisation of mineral assemblages in greenschist facies[6]. In this note, we shall present new isotopic age data on various rocks and minerals from Ile de Groix, hoping to delineate the time sequence of original magmatism, sedimentation and subsequent metamorphism.

Six phengitic mica samples were separated from metavolcanic rocks and three from possibly metatuffaceous sediments. They were analysed for Rb and Sr concentration and Sr isotopic compositions. The ages calculated from five whole rock–phengite pairs, two epidote–phengite pairs and two 0.705-phengite pairs are clustered in the range of 340 to 375 Myr (λ $^{87}\text{Rb} = 1.42\times10^{-11}\ \text{yr}^{-1}$) (Fig. 1). K/Ar measurements, by J. C. Hunziker, on four of these samples yield slightly lower ages (340 to 360 Myr), but are, nevertheless, within error of the Rb–Sr ages (Fig. 1); a paragonite gives 273 ± 14 Myr.

The mica ages could be interpreted as representing either the time of crystallisation or cooling[7], but the actual scatter of these age data suggests the effect of cooling. Thus the age of 375 ± 15 Myr is considered as a minimum for the crystallisation of phengitic mica and thus also for the time of high pressure metamorphism. The paragonite age is interpreted as the final cooling event.

This interpretation does not agree with Carpenter and Civetta[8]. They obtained K–Ar ages on three glaucophanes between 315 ± 11 and 329 ± 33 Myr and on four phengites between 327 ± 10 and 339 ± 10 Myr. The concordance of these results led them to conclude that both minerals were formed at the same time about 335 ± 20 Myr ago during an episode of high pressure metamorphism.

Their data, however, as well as our results, show that phengites give systematically older ages than glaucophane. An independent measurement by H. Maluski[9] by the $^{40}\text{Ar}/^{39}\text{Ar}$ method has also confirmed the lower age of glaucophane (320 ± 8 Myr) compared with phengites. This difference is significant and consequently the ages of 320 ± 8 and 335 ± 20 Myr cannot represent the time of high pressure metamorphism.

This relation between glaucophane and cogenetic phengite has also been found by Coleman and Lanphere[10], Suppe and Armstrong[11] in the Californian blueschists and by Hunziker[12] in Alpine high pressure metamorphic terrains. These authors suggest that glaucophane has lost argon during later metamorphic or tectonic events, and that glaucophane ages may postdate high pressure metamorphism.

Such an interpretation seems to apply to the data from Groix; glaucophanes are often aligned parallel to early isoclinal fold axes, probably synchronous with high pressure metamorphism, but subsequently, they often became reoriented about axes of later folding and underwent recrystallisation. This suggests that 320 Myr glaucophane ages, in fact, record the effect of this later folding phase, and that the high pressure metamorphism occurred at, or before 375 Myr ago.

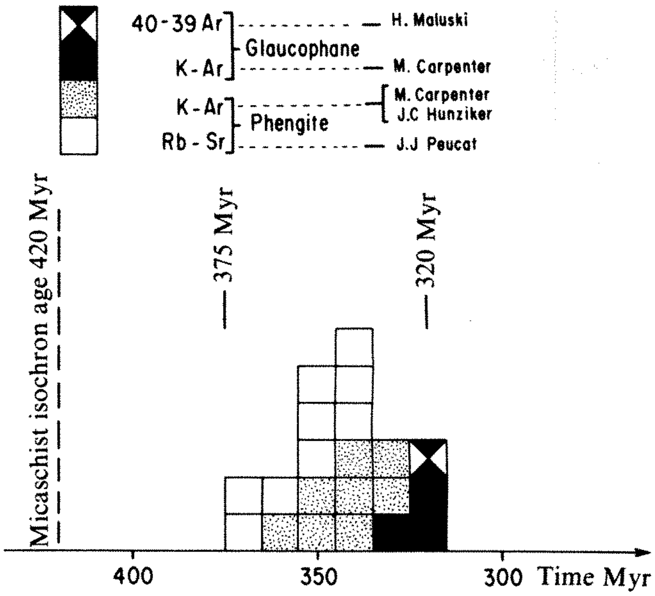

Fig. 1 Rb/Sr and K/Ar ages for phengites and glaucophanes. $^{40}\text{Ar}/^{39}\text{Ar}$ step release age for glaucophane.

Whole rock Rb–Sr isotopic data on four micaschists have been previously published by Vidal[13]. New measurements on two micaschists without glaucophane and on two with glaucophane as well as these four data of Vidal allow us to construct a reference isochron with an age of 420 Myr (Fig. 2).

Among the basic igneous rocks, one data point (Fig. 2) (an alkali-rich rock characterised by the presence of abundant phengitic mica: 2444) also lies near, or on, the micaschist isochron. However, most metabasaltic rocks have very low Rb/Sr ratio (<0.25) and as their $^{87}\text{Sr}/^{86}\text{Sr}$ ratios lie between 0.7052 and 0.7101, they do not allow construction of an isochron. Assuming an age of 420 Myr for the time of metamorphism, the calculated initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios range from 0.705 to 0.709. Reasons that might explain this scattering are: possibly seawater alteration effects, contamination from sediments, heterogeneous igneous source material with large differences in initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios. Preliminary chemical data on major and trace elements suggest that the original source rocks are produced from alkali-basalts and tholeiites, but higher initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios values suggest possible contamination.

We do not think that this age of 420 Myr reflects the sedimentation age because this would certainly have been disturbed by two metamorphic episodes[14,15]. Near Groix, very similar protoliths (Pouldu series) are cut by the Moëlan granite[16] dated at 474 ± 2 Myr (λ $^{87}\text{Rb} = 1.42\times10^{-11}\ \text{yr}^{-1}$) by Vidal[13]. Sedimentation here, therefore, pre-dates this Ordovician age.

Assuming that the 320 Myr age on glaucophane reflects the effects of a later metamorphic and deformation event, it is possible to associate this event with retrograde metamorphism. Consequently, the age of 420 Myr could reflect the high pressure–low temperature metamorphism, or a previous episode of metamorphism, or dewatering of sediments.

A pre-high pressure–low temperature metamorphism is possible, but is not recognised from petrographic study. When we take into account that the age 420 Myr is deduced from a reference isochron and that the 360–375 Myr mica ages are cooling ages, then the difference between these two ages does not necessarily imply two separate periods of metamorphism. Hence we interpret the age of 420 Myr as representing the time of high pressure–low temperature metamorphism, or possibly, the time of dewatering of sediments.

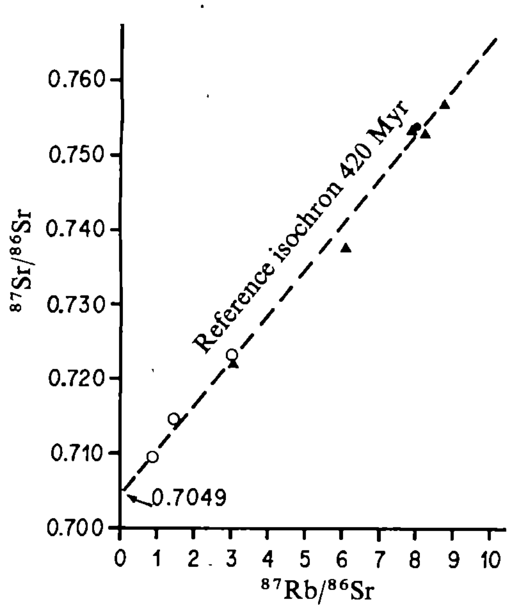

Fig. 2 Whole-rock reference isochron for micaschists: (○) micaschists with glaucophane, (▲) micaschists without glaucophane. Age calculated from seven points is 421±7 Myr with an ^{87}Sr/^{86}Sr initial ratio of 0.7049±3.10^{-4} (λ ^{87}Rb = 1.42×10^{-11} yr^{-1}). (●) Micaceous metabasic rock (2444).

In conclusion, the following metamorphic episodes can be delineated: (1) Pre-Hercynian period is characterised by the advent of high pressure–low temperature metamorphism about 370–420 Myr ago. The limits of this metamorphic period in South Brittany can be constrained by the study of Morbihan migmatites. The migmatisation affects an orthogneiss dated at 462±7 Myr by Peucat and culminates with emplacement of anatectic granites at 376±12 Myr (ref. 17). High pressure metamorphism and migmatisation events correspond with an important pre-Hercynian orogeny, possibly, with paired metamorphic belts of *circum* Pacific type, in which the basement was formed. (2) The Hercynian period produced partial retrogression of high pressure mineral asemblages into greenschist facies causing loss of argon in glaucophane. The continental basement was also affected by this retrograde metamorphism, especially near folds and shear zones. It is characterised by major plutonism *ca* 340–290 Myr ago. The thermal history of this area ends with cooling beneath 300 °C 290 Myr ago (Rb/Sr mica ages throughout south Brittany give 280–290 Myr) (ref. 18).

We thank Drs Ph. Vidal, B. M. Jahn and M. S. N. Carpenter for critical reading and helpful discussions. We are also grateful to Dr J. C. Hunziker who allowed us to use his preliminary results. We thank J. Cornichet and J. Macé for their assistance with Rb–Sr measurements.

^{40}Ar/^{39}Ar ages of a diabase sill and a basalt in the Central-Pacific Basin

The deep sea drilling project (DSDP) Leg 17 has covered the area of the Central-Pacific Basin south of the Mid-Pacific Mountains and east of the Marshall Islands. Since this region belongs to the magnetic quiet zone, no definite ages of oceanic crust could be assigned. Results of drilling at Site 166 (3°45.7′N, 175°4.8′W) and at site 167 on Magellan Rise (7°4.1′N, 176°49.5′W) have given estimates of crustal ages of about 120 and 135 Myr respectively from the basement fossils, which suggests that ages increase northward on this set[1]. Furthermore, the parallelism of linear bathymetric features around site 167 to the magnetic and bathymetric trends around site 166 has been interpreted by Winterer[1] to mean that they belong to the same spreading ridge system with an average spreading rate of 2–4 cm yr^{-1} for the crust between the two sites. Since sites 169 and 170 are located to the north-west of the sites 166 and 167 in the magnetic quiet zone, they were expected to give older ages, probably Jurassic, from the extrapolation of the trend stated above and by referring to the time scale of magnetic reversals[2]. It has been revealed, however, that at site 169 (10°40.2′N, 173°3.0′E) the oldest sediment recovered yields Albian age (100–104 Myr), which overlies basalt. At this site, about 8 m of diabase sill was drilled, which intruded Turonian (87–95 Myr) or Cenomanian (95–100 Myr) sediments[3]. At site 170 (11°48.0′N, 177°37.0′E), the oldest sediment overlied the basalt is also of Albian age[4]. These ages are much younger than those expected from ages obtained at sites 166 and 167, which may reflect the different history of the ocean floor from those at sites 166 and 167. To clarify this point, two igneous rocks were dated by ^{40}Ar/^{39}Ar method. Details of experimental procedures are described elsewhere[5].

The sample 169-6-2 is a diabase sill drilled at site 169 and relatively fresh among drilled samples, while the sample 170-16-2 is a basalt drilled at site 170, which was the lowermost one at this site. Results of ^{40}Ar/^{39}Ar dating are shown in Fig. 1*a* and *b*.

As shown in Fig. 1*a*, for the sample 169-6-2 the plot of the highest temperature fraction is clearly deviated to the higher ^{40}Ar/^{36}Ar ratio from the isochron, which indicates the existence of excess ^{40}Ar in this fraction. Excluding this point, however, other points form a good isochron of 90 Myr with the MSUM value of 1.428. This age is nearly

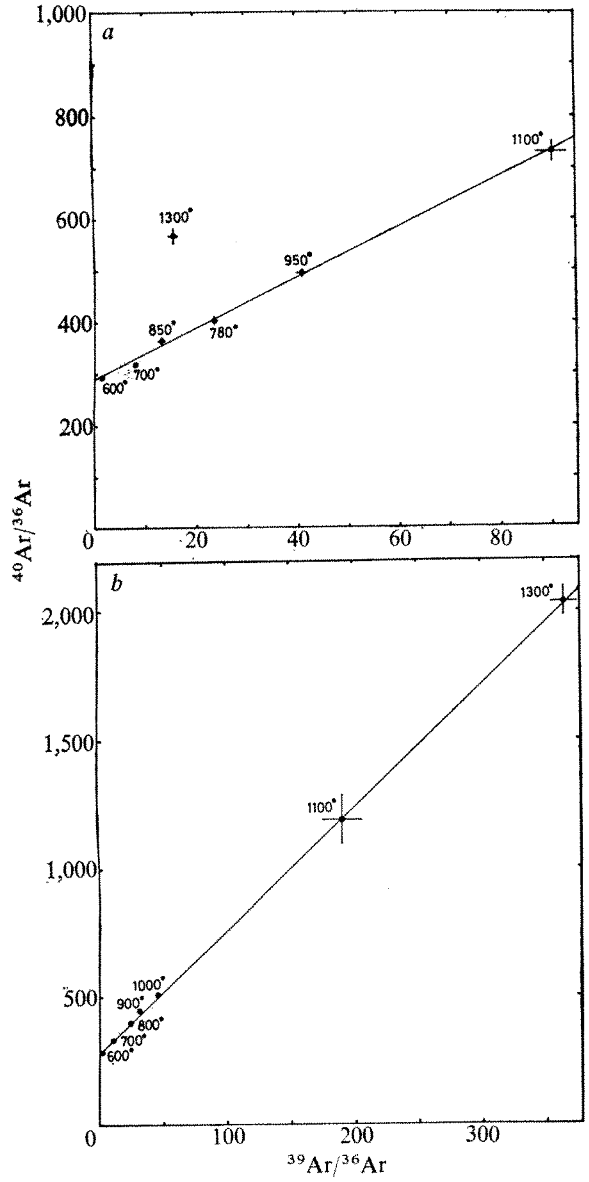

Fig. 1 ^{40}Ar/^{39}Ar isochron diagrams for Leg 17 samples. Samples were heated for one hour at each temperature which is indicated by figures at each plot. Horizontal and vertical bars at each plot indicate error range (one standard deviation) for each analysis. Bern 4M muscovite (18.5 Myr) was used as an age standard. (All necessary corrections including those for interference products have been made.) (*a*) Sample Leg 17–169–6–2; age: 90.0±3.5 Myr; intercept: 285.4±3.5, (*b*) Sample Leg 17–170–16–2; age: 97.2±2.5 Myr; intercept: 280.3±2.1.

the same or a little younger than that of intruded sediments. Petrologically the diabase has been regarded to have intruded as a sill rather than extruded as a flow[3]. Our results agree with this observation.

The ^{40}Ar–^{39}Ar isochron age of the basalt 170-16-2 is 97 Myr (Fig. 1*b*) and a little younger than that of the overlying sediments which contain late Albian radiolaria[4]. These basalts are reported to be altered[4], but stepwise-heating result has shown that it causes apparently no serious effect on the obtained age. The MSUM value for this sample is 1.605. Results for the sample 170-16-2 supports the middle Cretaceous age of basalt as estimated from the overlying sediments, which is much younger than Jurassic age which was expected. There are two possible explanations for this difference.

First, the basalt drilled at site 170 may be only a sill and not represent the true basement whose age is older than that obtained in this study. Bass *et al.* has interpreted the basalt as a sill of ocean island tholeiite from textural evidence and lack of glass or pillow structure[6]. In order to explain the existence of the magnetic quiet zone in this region, the crustal age should be in Jurassic and older than about 155 Myr, considering a long period of normal geomagnetic polarity at that time[2].

Secondly, the sample 170-16-2 may represent the basement rock, and the oceanic crust in this region might be really young—of middle Cretaceous age. Although the ^{40}Ar/^{39}Ar isochron age obtained for present sample is a little younger than that estimated for the overlying sediments, the difference may not be significant, considering its error range. Since a long period of normal geomagnetic polarity in Jurassic began about 108 Myr ago[2], the crustal age should be nearly the same or younger than about 108 Myr in order to explain the existence of the magnetic quiet zone. In addition to the age data, estimated from the lowermost sediments at sites 169 and 170, our present result is compatible with this interpretation. In this case, the crust in this region might be characterised by recurrent flows. In fact, many sills and/or dykes have been observed in the Mid-Atlantic Ridge area[7] and recurrent flows in the ocean floor may not be uncommon.

We have no preference between the two possibilities. Further deeper drilling is desirable in order to clarify the origin and formation ages of the Central-Pacific Basin.

One of us (I.K.) thanks the Ito Science Foundation for its financial support in this study.

Mercury emissions from chlorine-production solid waste deposits

Before 1970 the amount of Hg discharged to the environment from anthropogenic sources was estimated to be comparable with quantities derived from continental weathering processes[1]. As a result, however, of several well-documented cases of acute Hg contamination throughout the world, most large industrial sources have been identified and the discharge of Hg reduced to negligible amounts relative to natural aquatic and atmospheric sources. The natural atmospheric dispersion mechanisms of Hg overshadow input into the global environment by human activity, the latter being of prime importance in localised environments. The role of the chlor-alkali industry in global and regional Hg cycling has been repeatedly discussed[2–5], with the general conclusion that their contribution may be of limited importance globally but of particular concern to local and regional water and air quality[6].

Although limited studies have been published on losses of Hg from production processes in active chlorine plants[3,4] none have considered the problem of atmospheric and aquatic emissions from waste products which have been ponded or otherwise stored near active or inactive plants. The study reported here concerns mercury emissions from wastes stored near an inactive chlorine plant.

The study area is at the site of a large chemical manufacturing facility in the eastern United States which ceased operation in 1972 because of an inability to meet newly imposed state and federal water quality standards. Sodium bicarbonate and related by-products were produced by the ammonia soda process since 1894. The plant began production of chlorine and caustic soda using the Hg-cell process in 1952. Between that time and 1972 waste products from both processes were disposed of in large sludge basins, a procedure relatively common in this industry[2,4,7]. The disposal site, with a surface area of ~ 44 ha, is situated adjacent to a river (daily mean discharge = 8.34 $m^3 s^{-1}$) in an area enclosed on one side by a natural ridge and on the river side by dikes built of $CaCO_3$ waste and boiler ash generated in the $NaHCO_3$ process.

We collected air, water, and waste samples within the study area during the period 1974–1976. Solid and aqueous samples for Hg determination were handled and analysed according to standard flameless AAS methods[8]. Air samples for particulate and vapour Hg were collected using standard air filter and activated charcoal absorption techniques[9,10] respectively, and analysed as above.

The volatility of metallic Hg (Hg°) and many of its compounds suggests its presence in large scale waste deposits such as these to be a potential threat to local air quality. Waste material collected from the surface of the waste ponds was used in laboratory experiments to determine the emission of Hg° from a known surface area at controlled temperatures. Approximately 4 kg of waste material (bulk material concentration = 155 μg Hg g^{-1}) was slurried into a 13-litre spherical glass chamber and allowed to dry to a moisture level similar to that observed for the surface of the actual waste ponds (approximately 75% water by weight). Mercury-free air was pumped through the chamber over the waste surface at 1 litre min^{-1} and the filtered output air sampled for Hg°. The emission of elemental Hg vapour from the waste material was clearly related to surface temperature (Fig. 1) as expected. The nature of the relationship is similar to that between temperature and the saturation concentration of Hg° in air[2,11] suggesting that the mercury occurs in the waste material to a large extent as the elemental species. Comparative data on Hg emission rates from natural soils are scarce, although some authors have reported observing release from soils experimentally enriched with inorganic Hg[12–14]. Natural degassing rates of Hg on regional or global scales have been estimated based on input/output calculations[15,16] as ranging from 0.02 to 0.03 μg $m^{-2} h^{-1}$, while measured rates for mineralised soils[17] are as high as 1.7 μg $m^{-2} h^{-1}$. We have recently measured the loss of Hg° from mercury-contaminated surface soils (total Hg = 99 μg g^{-1}) collected within 1 km of a large active Hg mine, and found emission rates at 33 °C to be in the range of 1.4–1.7 μg $m^{-2} h^{-1}$. These values are two orders of magnitude lower than those we have measured in comparable conditions for the waste material (120–170 μg $m^{-2} h^{-1}$). The difference is probably related to the form of Hg present in the two samples; the mine site soil contains primarily HgS and HgO.

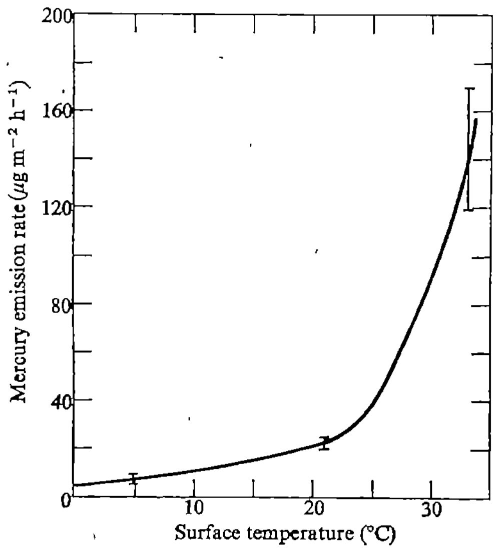

Fig. 1 Relationship between emission of vapour phase elemental mercury and surface temperature of waste material. The numerical relationship derived from a nonlinear least squares fit is $Y = a + b\exp(cX)$, where Y = emission rate in μg $m^{-2} h^{-1}$, X = surface temperature in °C, a = 6.40 (standard error = 1.59), b = 0.310 (standard error = 0.100), c = 0.190 (standard error = 0.00982).

Table 1 Daily mean concentrations of mercury vapour (Hg°) in air in vicinity of waste ponds under various meteorological conditions

0.5	96	29.4	991±2†	778

*Expressed as a percentage of the total sampling period (24 h) during which the sample location was downwind of the waste pond.
†Replicate samples.

Considering the waste deposits as an area source, we have applied a simple Gaussian diffusion model[18] to estimate 24 h mean concentrations of Hg vapour in the ambient air downwind of the source. The emission rates measured in controlled conditions (Fig. 1) were used in the model; mean wind speed directly over the pond area was assumed to be 1 m s^{-1}; the background air Hg concentration was taken as 10 ng m^{-3} (ref. 15). Given the simplicity of this approach, the close agreement between measured and predicted 24 h mean air concentrations in similar conditions (Table 1) can be taken as an indication that the entire surface area of the waste pond was emitting Hg vapour at a rate comparable to that measured in controlled experiments.

The levels of Hg° in air measured near the pond during periods of low air temperature (Table 1) were slightly elevated above those reported for large US cities[3,18]. The fact that these concentrations decreased to rural background levels[3] within 1.5 km of the waste disposal area is attributable to the ability of a well mixed atmosphere to dilute gaseous pollutants rapidly. However, during periods of higher air temperature, the concentration of Hg° measured near the pond area approached the US Environmental Protection Agency suggested standard for total Hg in ambient air (1,000 ng m^{-3}) (ref. 19). This compares with levels of 30–1,600 ng m^{-3} for air over natural Hg deposits and 10–28,000 ng m^{-3} for natural degassing and geothermal emissions[3]. The concentration of particulate Hg during this sampling period was surprisingly low (0.25–0.36 ng m^{-3}) considering the area in question, and reflected the stability of the waste pond surface to dust resuspension. The indication that essentially 100% of the Hg in air is in vapour form agrees with recently reported results[19].

The location of the waste ponds behind steep dikes along a riverbank and perched on the flank of a ridge is highly conducive to the leaching of soluble components of the waste by direct rainfall and by runoff from the adjacent ridge. Clay tiles installed beneath the dikes serve to drain the waste from the bottom while overflow structures drain the ponds from the surface and intermediate depths. Discharge of waste leachate

§Measured flux on this day was 14.3 $g\ d^{-1}$.

through these structures and many intermittent seepages flow directly into the adjacent river. Our own direct measurements of leaching rates of Hg from the waste area were limited to periods of very low river discharge, since most of the tile drains were submerged and thus inaccessible for sampling and flow measurement during higher flows. Consequently, we also applied a mass balance approach to estimate net fluxes of mercury to the adjacent river (Table 2) Using mercury concentrations and stream discharge measurements taken between 1974 and 1976 at points immediately upstream and downstream of the waste pond area[10], we calculated net fluxes of mercury as the difference between upstream and downstream fluxes. To the extent that mercury accumulates in river bed sediments during periods of low river discharge, or is flushed from river bed sediments during periods of high river discharge, mass balance calculations based on instantaneous measurements will either underestimate (at low discharge) or overestimate (at high discharge) the actual leaching rate of mercury from the waste ponds. Direct measurements of all accessible flows of waste leachate into the adjacent river during a period of low river discharge offered some reasonable verification of a mass balance calculation made for the same period. On one day the total measured flux of mercury was 14.3 $g\ d^{-1}$ while the calculated net flux was 28.4 $g\ d^{-1}$. The lower measured flux probably results from our inability to locate and measure all leachate seepages rather than from an overestimate by the mass balance calculation.

Our estimates of aquatic fluxes of mercury from the waste pond area indicate considerable variability in the apparent leaching rate of mercury from the waste, but demonstrate a good correlation ($r = 0.86$; $P < 0.01$) with discharge of the adjacent river which responds primarily to local rainfall in the upstream 575 km^2 catchment. However, it is not clear whether this correlation results from a direct dependence of mercury leaching rate on rainfall input or from the dependence of bed sediment erosion on river discharge. Both processes probably contribute to higher net mercury fluxes from the waste pond area during periods of higher river discharge.

Using simple regression analyses we have obtained functions which estimate both surface emission of Hg°, based on air temperature, and aquatic leaching of Hg, based on streamflow. Applying these relationships to daily streamflow and hourly temperature data for the waste pond area for a typical year (October 1973–September 1974), we have calculated the estimated annual loss of mercury from the waste disposal site by both the atmospheric and aquatic pathways. Losses were nearly equally divided between these pathways $36\pm4\ kg\ yr^{-1}$ (predicted sum±the estimated standard error of the sum of predicted fluxes) atmospheric emission of Hg and $39\pm2\ kg\ yr^{-1}$ aquatic emission of Hg. The occurrence of high streamflow during cold winter months resulted in predominance of the aquatic pathways during winter and predominance of the atmospheric route during summer months. This results in a relatively uniform emission of Hg from the waste deposits over an annual cycle.

The estimated total annual flux of Hg from this inactive plant, $75\pm5\ kg\ yr^{-1}$, is approximately 6% of the US Environmental Protection Agency standard for emission of Hg to air and water from active chlorine plants situated in riverine environments. Recently reported losses of Hg to the atmosphere and surface waters by Swedish chlor-alkali plants were, however, in the range of 150–1,400 $kg\ yr^{-1}$ (refs 2, 6). Values for US plants are estimated to range up to 1,100 $kg\ yr^{-1}$ (ref. 3). Estimates of the capability of improved technology to reduce Hg emissions from active plants indicate a possible 40% decrease in emissions by these routes[3], resulting in Hg losses from the more efficient operations (that is, those reported above for Swedish plants) which would be similar to those reported here for waste disposal ponds alone.

At present the most significant mercury waste problem in this industry involves disposal of large quantities of solid waste materials. Thus, given the common disposal practice of ponding solid wastes, along with the residence time of Hg in existing large scale waste deposits (conservatively estimated as 100 years for the waste area studied here)[10], it becomes apparent that the role of such residual waste deposits in local Hg cycles will continue to grow in relative importance.

Dissolved aluminium concentration in sea water

DISSOLUTION of clay minerals in seawater results in aluminium concentrations in solution (1.3–7.5 μg Al per l) which are similar to those found in coastal waters but considerably higher than the probable value of the aluminium concentration in open ocean surface waters (0.5 μg Al per l). This note compares the results of precipitation and dissolution and investigates the mechanism of the dissolution of aluminium from three different clay minerals. Our results show that bottom and suspended clay sediments probably act as a source of dissolved aluminium to sea water, whereas removal below clay solubility predictions is probably the result of biological activity, as is the case for silicon, the other main constituent of most rocks and minerals.

Recent results from the North Sea[1] and the North Atlantic[2] show that away from the influences of aluminium-rich freshwater sources and higher coastal concentrations of suspended matter the concentration of aluminium in seawater will be approximately 0.5 μg l^{-1}. This level is more than an order of magnitude lower than that predicted by alumina–silica coprecipitation experiments[3], which showed that at levels of silica which occur naturally in seawater, the solubility of aluminium is much reduced below that which is stable in silica free seawater. These experiments[3] may have produced erroneously high levels due to the inclusion of particulate aluminium in the analysis results and the failure of the experiments to reach complete equilibrium.

We carried out the following experiments (a fluorometric analysis method was used which is insensitive to aluminium in particulate matter[4].) The fractions of the clays of less than 2 μm were separated by centrifugation, and suspensions containing 10 g of clay in 1 l of sea water were prepared in polythene bottles. The *p*H of the suspensions were adjusted to *p*H 8.1 with a few drops of sodium carbonate solution. They were then maintained at 20 °C in the dark and continually shaken for four months. Aliquots were withdrawn periodically, centrifuged and filtered through 0.1-μm membrane filters before the aluminium and silicate analyses were carried out. The clays and seawater reached a steady state within three months. No trends are discernible in the measurements made at three and four months. After four months the *p*H of the solutions were readjusted to *p*H 8.1 using dilute sodium hydroxide, and maintained at this *p*H by daily control for one week before the aluminium and silicate concentrations were measured. The conditions were again changed by lowering the temperature to 3 °C and the new conditions were maintained for one week before the analyses were carried out. The results of this experiment are summarised in Table 1.

The pattern of silica dissolution followed that observed in previous studies[5]: a rapid initial rise in the concentration was followed by a more gradual increase over several weeks. The change in aluminium followed a completely different path after the initial sharp increase. For each of the three clays the highest aluminium concentrations were measured in the first aliquot to be withdrawn. The concentrations then fell gradually reaching apparent equilibrium in two months. To see to what extent the fall in aluminium concentrations observed was due to changes in *p*H, a second experiment was carried out using kaolinite, the *p*H being maintained at *p*H 8.1. The results of this experiment are shown in Fig. 1. The decrease in aluminium concentrations observed in the first experiment were not simply due to *p*H changes. Also, there was no evidence for a simple control of the aluminium concentration by silicate as the aluminium concentration continued to decrease after the maximum silicate concentration was reached. The plot of aluminium concentration against $t^{1/2}$ is approximately linear which suggests the rate controlling step is a diffusion process, which is amenable to further study.

When the results of these experiments (1.3–7.5 μg Al per l) are compared with those for precipitation (8–15 μg Al per l) (ref. 3) we see that dissolution, as would be expected for approaching equilibrium from the opposite direction, gives slightly lower values than precipitation. Both sets of results predict much higher concentrations of aluminium in seawater containing an average amount of silica than have actually been observed in open seawaters. In coastal waters aluminium concentrations of the predicted magnitude have been recorded (maximum levels observed in refs 1 and 2 are 5.5 and 4.6 μg Al per l respectively). The inference from comparing the results for open seawater and coastal seawater is that away from the higher suspended matter concentrations in coastal waters, the clay concentration is not sufficiently great to maintain the aluminium concentration in competition with biological activity which is removing aluminium from the water. A number of pieces of evidence support the idea of aluminium being removed from solution in some part of the life cycle of siliceous diatoms. Diatom frustules are known to contain aluminium[6], the source of which is uncertain. Possible montmorillonite structures have been observed in the frustules from living diatoms thought to be uncontaminated by detrital clays[7]. This suggests that aluminium

†Results: (1) after 36 h; (2) after 3 months; (3) end of 4 months, final *p*Hs—Kaolinite 7.35, Fireclay 7.69, Montmorillonite 7.35; (4) after 4 months plus 1 week at *p*H 8.1; (5) after 4 months plus 1 week at *p*H 8.1 and 1 week at *p*H 8.1 and 3 °C.

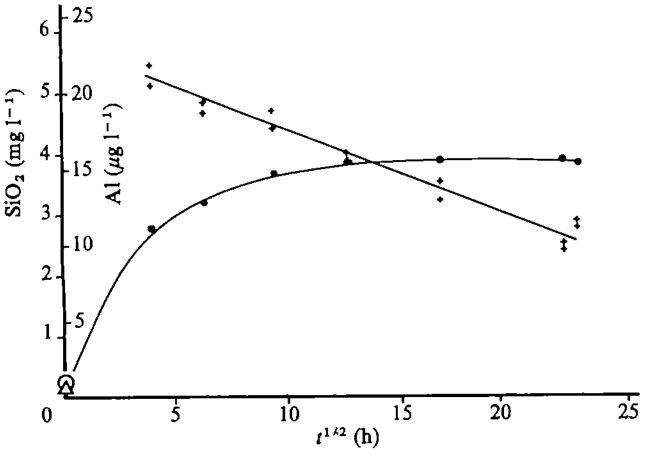

Fig. 1 Rate of dissolution of silica (●) and aluminium (+) from duplicate suspensions of kaolinite, 10,000 mg l^{-1} in sea water at pH 8.1 and 19±1 °C. For silica the difference between the samples taken is smaller than the data point. Initial concentrations of: ○, silica 0.1 mg SiO_2 l^{-1}; △, aluminium 0.3 μg Al l^{-1}.

removal may be an active biological process as the removal from biologically productive waters seems to be for other trace metals[8,9]. However, evidence also exists for the formation by adsorption on to the frustules of dead diatoms of alumino-silicate phases[10]. Further work is required to establish how strongly aluminium is adsorbed by siliceous diatom remains and what the balance is between that and active biological removal.

Optimal foraging in great tits (*Parus major*)

OPTIMAL foraging theory[1-5] is based on the supposition that animals have been designed, by natural selection, to behave in a way that will maximise their inclusive fitness and that in terms of foraging this goal may be approximated by maximising the net rate of energy intake while feeding[1-4]. Therefore, given the constraints of any particular situation it is possible to predict how an animal ought to behave while foraging. I have tested an optimal foraging model which predicts how a predator should exploit patchily distributed prey. The results are consistent with the predictions of the model.

The prey of most predators are not scattered randomly throughout the environment[6] but occur in aggregations, which I call patches. To exploit these patches efficiently a predator needs to 'decide' which patches to visit and when to move from one to another. If the quality of a patch cannot be predicted in advance the problem simply becomes: how long is it best to remain in each individual patch? Several authors have produced similar models describing the optimal solution to this problem[7-9]. Owing to depletion of prey, the capture rate within a patch is likely to be a decreasing function of the time spent there[10]. This means that if a predator stays for too long its capture rate will fall below that which could be achieved by moving to the next patch. Conversely, if it does not stay for long enough it will spend too large a proportion of its time travelling. The optimal solution is that the predator should move when its capture rate within a patch drops to a threshold equal to the average capture rate for the environment as a whole. This critical threshold is called the marginal capture rate[7] (Fig. 1).

The optimal solution (Tp(opt)) is affected by changes in either the curve $f(Tp)$ or the time taken to travel between patches (Tt). In my experiments I manipulated the latter and kept the former constant so that it is possible to define the relationship between Tp(opt) and Tt as follows.

Assuming the curve $f(Tp)$ is an exponential of the form

$$f = Q[1-\exp(-mTp)] \qquad (1)$$

(where f is average net energy intake; Tp is time in patch; m and Q are constants), the rate of food intake after a length of stay Tp is given by

$$\mathrm{d}f/\mathrm{d}Tp = Qm\exp(-mTp) \qquad (2)$$

The optimal predator should leave a patch when its capture rate falls to the average capture rate for the environment[7,8]. That is when

$$\mathrm{d}f/\mathrm{d}Tp = f/(Tt+Tp(\mathrm{opt}))$$

where Tt is mean travel time.

Therefore

$$Qm\exp(-mTp(\mathrm{opt})) = f/(Tt+Tp(\mathrm{opt})) \qquad (3)$$

Substituting equation (1)

$$Qm\exp(-mTp(\mathrm{opt})) = Q[1-\exp(-mTp(\mathrm{opt}))]/(Tt+Tp(\mathrm{opt})) \qquad (4)$$

Rearranging this gives

$$Tt = 1/m[\exp(mTp(\mathrm{opt}))]-1)-Tp(\mathrm{opt}) \qquad (5)$$

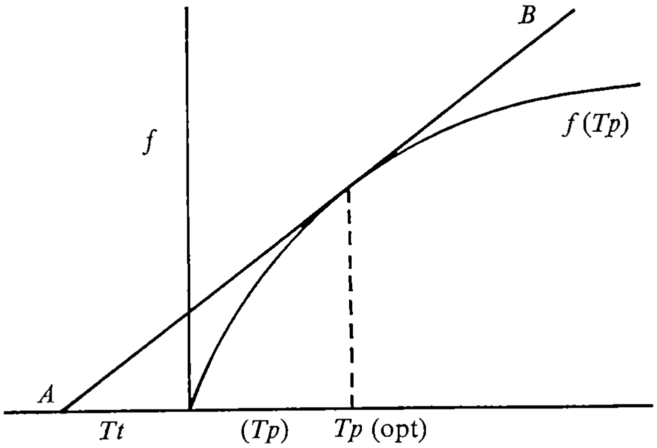

Fig. 1 Graphical representation of a model of optimal patch use[7,8]. The curve $f(Tp)$ represents the average net energy gain (f) as a function of the time spent in each patch (Tp). The abscissa is extended in the negative quadrant to a distance Tt which is the mean time taken to travel between patches. The maximum average net rate of food intake that is obtainable can be determined by constructing the tangent to $f(Tp)$ from point A. The predator ought to leave each patch after time Tp(opt) in order to maximise its average capture rate.

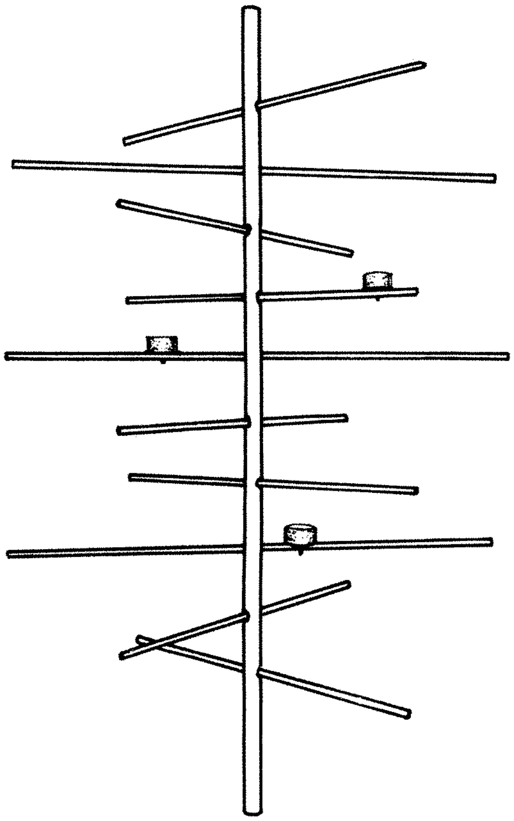

Fig. 2 An experimental 'tree'.

This relationship makes it possible to test the predictions of the model quantitatively.

I performed the experiments on six wild caught great tits (*Parus major*). The apparatus consisted of an aviary (4.6 m × 3.7 m), containing five artificial trees (Fig. 2). Each tree supported six patches. Patches were made from 4-cm lengths of plastic drainpipe (6.5 cm diameter), which were sealed at one end. The patches were filled with sawdust in which I hid the prey, six quarter sections of mealworm.

I subjected each bird to two types of 'environment' which were identical in all respects except for the time and energy cost of travelling between patches. Ideally these costs should have been increased by placing the patches farther apart but it was impossible to separate them by large enough distances within the confines of the aviary. Instead, I covered each patch with a cardboard lid which the bird had to remove before it began foraging. There were two types of lid. One rested on top of the drainpipe and could easily be flipped off, the other fitted just inside the rim and had to be prised out. Each experimental environment contained patches with lids that were either all 'hard' or all 'easy' to remove, these differences corresponding to long and short travel times respectively.

I performed six trials on each bird in each environment. Every trial was preceded by 2 h of food deprivation and was terminated when the bird had foraged for 10 min. Satiation and overall depletion of the environment had no observable effect within this period. Throughout each trial I watched the bird from behind a one-way mirror and recorded its behaviour on a Dawkins' behaviour organ[11].

Table 1 shows that the changes in travel time have a significant effect on the average capture rate and the average time spent in each patch. To calculate $Tp(\text{opt})$ from equation (5) it is necessary to know the formula for the curve $f(Tp)$ (Fig. 1). I determined this curve by calculating the mean number of prey caught as a function of the time spent searching in a patch. For each bird the best fit was provided by an exponential of the form described previously (equation (1)). Figure 3 shows the actual relationship between the mean travel time and the mean time spent per patch, for each bird in both environments. The dotted curve is the optimal solution calculated using equation (5) and the mean $f(Tp)$ curve for all six birds. Most of the data points lie above this curve which indicates that the birds tended to stay in each patch for too long. This can be explained by the fact that the curve $f(Tp)$ only takes into account the average gross rate of energy intake. If adjustments are made for the energetic costs of travelling and searching the relationship in equation (5) can be rewritten as

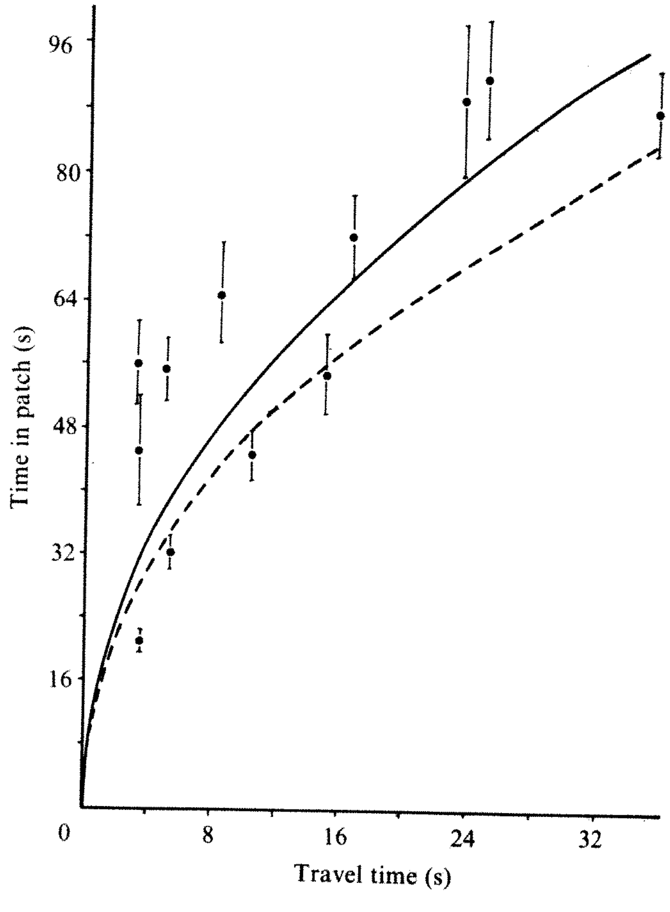
$$Tt=[KQ(1-\exp(-mTp)(1+mTp))]-P/(KQm\exp(-mTp)-B)$$

Table 1 Summary of principal variables in each environment

Variable	'Hard' environment	'Easy' environment	Paired t value	Significance level, 5 d.f.
Mean intercatch interval (s)	15.37 (1.37)	14.41 (1.87)	0.98	NS 2-tailed
Time in patch (s)	73.67 (8.06)	45.80 (6.77)	2.95	$P < 0.02$ 1-tailed
Handling time (s)	6.79 (0.60)	9.62 (1.65)	1.51	NS 2-tailed
Travel time (s)	21.03 (3.65)	4.76 (0.80)	4.73	$P < 0.002$ 1-tailed
Average capture rate (prey per s)	0.0264 (0.00277)	0.0366 (0.00541)	3.52	$P < 0.02$ 1-tailed

Averages of data for all six birds. The figures in brackets are standard errors. The average capture rate was determined by dividing the total number of finds in each trial by the total foraging time. The mean intercatch interval within a patch is the average time spent searching for each prey item. Handling time is the time taken to manipulate and eat a prey item. Time in patch and travel time are explained in the text.

Fig. 3 The relationship between the mean travel time and the mean time spent in each patch, for each bird in both experimental treatments. The vertical bars represent the standard error. The dotted curve shows the optimal solution derived from equation (5) and the unbroken curve shows the optimal solution after making adjustments for energy expenditure. $P = 0.697$ cal s^{-1}; $B = 0.155$ cal s^{-1}; $k = 56$ cal; $Q = 6.3587$; $m = 0.00813576$.



where P is energy cost of travel (cal s^{-1}), B is energy cost of searching (cal s^{-1}), K is calorific content of prey (cal). The basal metabolic rate (BMR) of a great tit was calculated using the equation of Aschoff and Pohl[12]. Estimates of the energy requirement for flight and feeding were taken as 9 × BMR and 2 × BMR respectively[13,14]. The solid curve in Fig. 3 shows the optimal solution based on net energy intake. It is not significantly different from the observed data. (Paired comparisons $t = 1.65$ ($t_{0.05} = 2.20$).)

These results show that great tits can exploit patchily distributed prey in a manner predicted by optimal foraging theory. Previous attempts to test this type of model[15,16] have been based on qualitative predictions, whereas I tested a quantitative relationship. The results imply that the birds can estimate both their instantaneous rate of intake within a patch and the average rate of energy intake over their environment as a whole. Unfortunately this concept of 'environment' is ill defined and it is difficult to know over what sort of time or area the birds might be averaging. One possible solution is that they have a memory window which produces a sliding average over the last few patches or minutes. In a constant environment a large window would result in an accurate measure of the average capture rate. In a fluctuating environment, however, a very large window could result in the predator adapting too slowly to changes in prey density. It seems likely that there is an optimal size for this memory window, and experiments to determine its size in great tits are underway.

Nature and precursors of juvenile hormone-induced excessive cuticular melanisation in German cockroach

GROWTH in insects proceeds through a number of moults, when the old cuticle is shed and a new one synthesised. Within few hours of ecdysis, the cuticle hardens and develops the characteristic colour pattern. When we treated German cockroach *Blattella germanica* (L.) nymphs with insect juvenile hormone (JH) 12 h before ecdysis, the resulting nymphs or adults developed excessive black coloration all over their bodies, obliterating the normal colour patterns[1]. The nature of this visible change was unknown[2,3]. Here we show for the first time that the excessive coloration, following JH treatment, is caused by melanin, and that dopamine or catechol seems to be involved in the hormone-influenced pathway.

The striped pattern of the dorsal plate (pronotum, Fig. 1) provided ready identification of melanised cockroaches. When a melanised nymph moulted into an older nymph or adult, the abnormal coloration was lost together with the old cuticle. Since only the outer layers of the integument are shed at the moult, this meant that the dark pigment was contained in these outer layers and not in the underlying epidermis. Cross sections of the cuticles (Fig. 2) confirmed that the pigment was located in the exocuticle, and that it was present even in areas that are normally devoid of pigment. We isolated the black pigments from the normal and melanised cuticles and studied their infrared spectra in comparison with that of synthetic melanin (Fig. 3). We found the cuticular black pigments to be quite comparable with the synthetic melanin and that the spectra from normal and melanised cuticles were identical. We therefore determined the amounts of melanin in the normal and melanised cuticles fluorimetrically[4], and found that the melanised cuticles contained 6.5 mg melanin (per g dry cuticle) compared with 4.8 g in the normal cuticles—a 35% increase.

We then proceeded to identify the precursors that might be on the pathway to excessive melanin biosynthesis. We

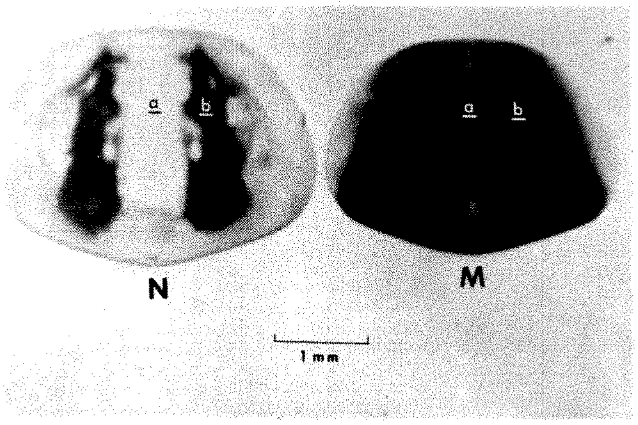

Fig. 1 Pronota of normal (N) and melanised (M) *Blattella germanica* adults showing the non-melanised (*a*) and melanised (striped, *b*) zones in normal adult and the corresponding zones in melanised adult. Synthetic *Cecropia* juvenile hormone, methyl-10,11-epoxy-7-ethyl-3,11-dimethyl-2,6-tridecadienoate, (or any of its mimics[8]) was applied topically (1.5 μl), by injection (0.33 μl), or by treating the food (200 p.p.m.).

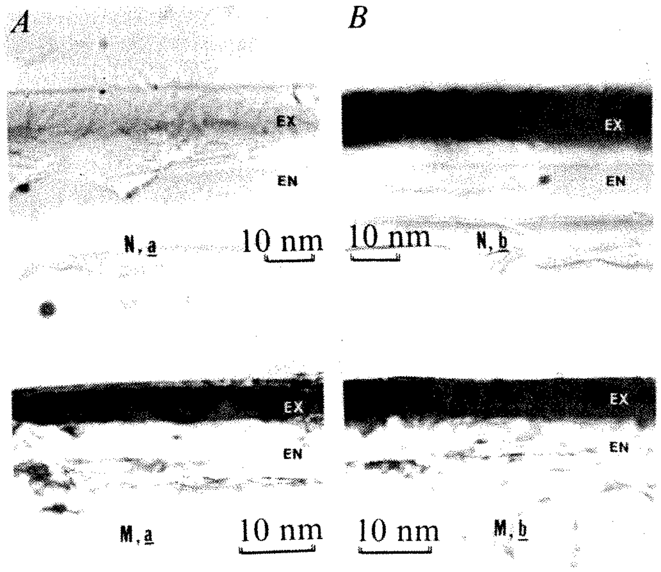
Fig. 2 Cross section of pronota of normal (N) and melanised (M) *Blattella germanica* adults; 10 μm, unstained. The clear zones (*A*) and striped zones (*B*) of the normal and melanised pronota are compared. Note the presence of melanin in zone *a* of melanised cuticle obliterating the normal melanic pattern. EN, Endocuticle; EX, exocuticle.



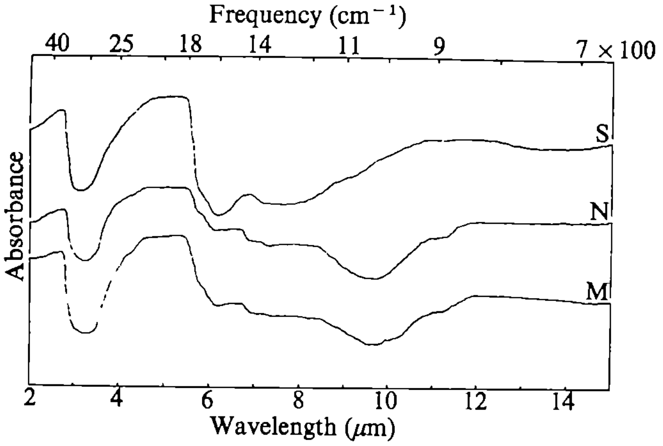


Fig. 3 Infrared spectra of synthetic melanin (S) and cuticular melanins of normal (N) and melanised (M) *Blattella germanica* adults using KBr disks containing 1% melanin. Dried cuticles were hydrolysed in acid and melanin was extracted in alkali[9-11].

incubated the fresh, soft, untanned cuticle (with the underlying epithelium intact) from normal cockroach in a tissue culture medium[8] modified by deleting tyrosine, tryptophan, phenylalanine, and foetal calf serum. Treated media were prepared by selectively incorporating the substrates and/or inhibitors into the culture medium—all at a final concentration of 3×10^{-3} M and *p*H 7.0. The media were oxygenated for 5 min through a fine capillary tube before introducing the cuticle. After incubating in the media for 5–10 h at 35 °C, the cuticles were washed in 95% ethanol and the coloration observed. The presence of tyrosine alone was adequate for the development of normal colour pattern. This could be inhibited, however, by either diethyldithiocarbamate (an inhibitor of tyrosinase[6], EC 1.14.18.1) or 1-(DL-seryl)-2-(2,3,4-trihydroxybenzyl) hydrazine HCl (an inhibitor of dopadecarboxylase[7], EC 4.1.1.28), showing that the cuticle normally contains all the required enzymes for melanin biosynthesis. Also, there was no need for JH in the medium. If either dopamine or catechol was provided in lieu of tyrosine, there was excessive melanisation similar to that observed in the JH-treated individuals. It is possible that the exogenous JH interferes with the timely autoinhibition of tyrosinase *in vivo* leading to unrestricted melanisation. Alternatively, a more readily utilisable precursor like dopamine is made available to the integument by induced synthesis, activation of stored molecules, or increased transportation. Absence of JH, which is generally the case at the time of moulting, seems to be a natural prerequisite for the normal colour development.

Simultaneous recording from several neurones in an invertebrate central nervous system

THE ability to monitor activity in many neurones simultaneously might provide a powerful tool for solving certain problems in neurobiology. There are several changes in the optical properties of a neurone that occur during an action potential[1-3] that might be used in an apparatus that could monitor spike activity in many neurones simultaneously. Although the changes in intrinsic (native) optical properties have been useful in other instances where an optical measurement of membrane potential was desired, larger signals were needed for this application. Therefore, a search was begun for extrinsic probe molecules which could serve as sensitive molecular transducers in stained membranes, transforming changes in membrane potential into changes in light intensity[4,5]. In earlier experiments we demonstrated changes in fluorescence[6] and absorption[7] during action potentials in individual neurones of a segmental ganglion from the leech, *Hirudo medicinalis*. In those experiments the ganglion was stained with a merocyanine dye[8]. In the experiments described here, carried out on the supraoesophageal ganglion of the barnacle, *Balanus nubilus*, the absorption change of a new merocyanine-oxazolone dye[9,10] was used. In measurements on squid giant axons, the signal obtained with the new dye was five times larger. In addition, the photodynamic

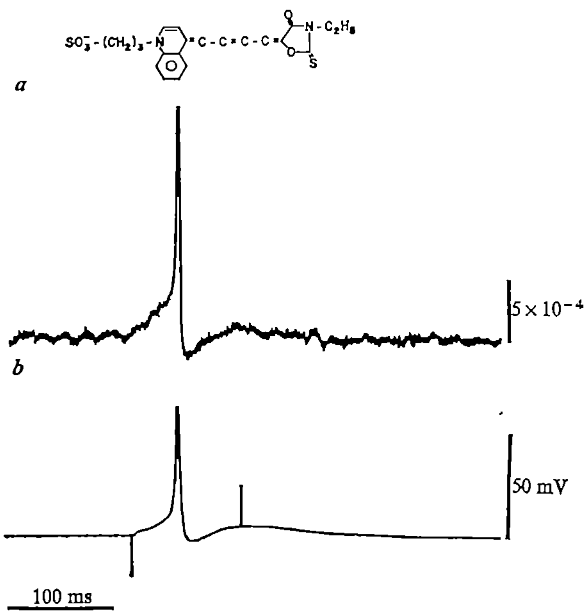

Fig. 1 The change in absorption (*a*) during an action potential (*b*). The structure of the merocyanine-oxazolone dye used in these experiments is shown at the top. The action potential size and time course were unaffected by turning on the light; no photodynamic damage was detected in the barnacle experiments even though the saline was equilibrated with air. The direction of the arrows to the right of the optical traces indicates an increase in absorption and the length of the arrow represents the stated value of the change in absorption divided by the resting absorption. An interference filter with peak transmission at 720 nm and width at half-height of 30 nm was positioned between the light source and condenser lens to restrict the measurement to wavelengths where the signal was largest in squid experiments. The output of each photodetector was amplified, limited to a bandpass of 1 Hz–0.3 kHz, and then displayed on a storage oscilloscope; permanent records were made with a Polaroid camera. The records were traced from enlargements of the original photographs. The ganglia were pre-incubated with a 1.5 mg ml^{-1} solution of collagenase in barnacle saline[11] for 5 min. The experiments were carried out at room temperature, 20–23 °C.

damage[8,11] associated with photochemical effects of intense illumination in the presence of dye and oxygen was 100 times smaller with the new dye.

To measure the absorption of light by individual neurones, an enlarged image of the ganglion was formed with a ×20, 0.4 n.a. objective using a Leitz Ortholux II microscope. Light guides (Schott, LST, clad glass rod) were used to carry the light from images of the individual neurones to individual photodiodes (PV 100A, E.G. & G. Inc.). The light guides and photodiodes were fixed to magnets on a stainless steel annulus above the image plane. The tips of the light guides had diameters of 1.5 mm and were positioned over the images of neurones by moving the magnets. The sizes of the large neurones on the dorsal surface of the ganglion were between 40 and 90 μm.

The barnacle ganglia were incubated for 20 min with a 1 mg ml^{-1} solution of the merocyanine-oxazolone dye shown in Fig. 1 (available as NK 2367 from Nippon Kankoh-Shikiso Kenkyusho, Okayama, Japan). The dye solution was then replaced with saline and an individual neurone impaled with a microelectrode. The tip of a light guide was positioned over its image, and a depolarising current was then passed through the microelectrode to stimulate the neurone. A simultaneous optical and electrode measurement is shown in Fig. 1. The change in intensity at the peak of the action potential divided by the resting light level was only about 10^{-3} and was often smaller. Even so, the signal-to-noise ratio in Fig. 1 is greater than 10 : 1. But, it was only after considerable effort[13] that we were able to reduce the noise from mechanical vibrations and other optical disturbances so that most of the noise in Figs 1 and 2 results from random arrival of photons at the photodetectors (shot noise[14]). Significant improvements in the signal-to-noise ratio can be achieved only by modifying the apparatus to increase the intensity reaching the photodetectors or by finding more sensitive dyes.

The signal-to-noise ratio illustrated in Fig. 1 was large enough so further experiments were carried out to determine whether synaptic potentials could also be detected optically. In neurones with excitatory or inhibitory synaptic potentials of 10 mV or greater, we could reliably detect the synaptic events in the optical trace. In the best circumstances, synaptic potentials of only 4 mV could be detected optically[13].

In the same experiment as that shown in Fig. 1, seven additional light-guide-photodiodes were positioned over the images of seven other neurones so that the activity of eight neurones was monitored simultaneously. In addition to the action potential in the impaled cell (7), there were spontaneous action potentials in two other neurones (1, and 4). We are confident that the absence of spikes in the remaining traces results from the absence of action potentials in those cells. (In several experiments, when a nerve root was stimulated with a suction electrode, optical spikes, presumably representing antidromic action potentials, appeared in previously silent neurones. These experiments are reported more fully in ref. 13.)

The magnitude of the optical signal will depend on several factors including membrane area and the amount and site(s) of dye binding in addition to the magnitude of the change in membrane potential. Since it is difficult to evaluate each of these parameters, it is not possible at present to determine the magnitude of the potential changes from these optical measurements; only information about the time course and the direction of the potential changes is obtained. Neither pharmacological effects nor photodynamic damage due to the merocyanine–oxazolone dye were detected in experiments on barnacle ganglia. Our evaluation of such effects is preliminary, however.

We think that the apparatus used in the experiment shown in Fig. 2 can be expanded so that 20 neurones are monitored simultaneously. It may be possible, using an electronic image detector positioned at the objective image plane, to develop an apparatus that monitors activity in 50–100 neurones. The ability to monitor activity from many cells may prove valuable in helping to determine the functional connections between neurones in nervous systems with a small number of neurones. Experiments designed to determine the neuronal basis of very simple behaviours might also be facilitated.

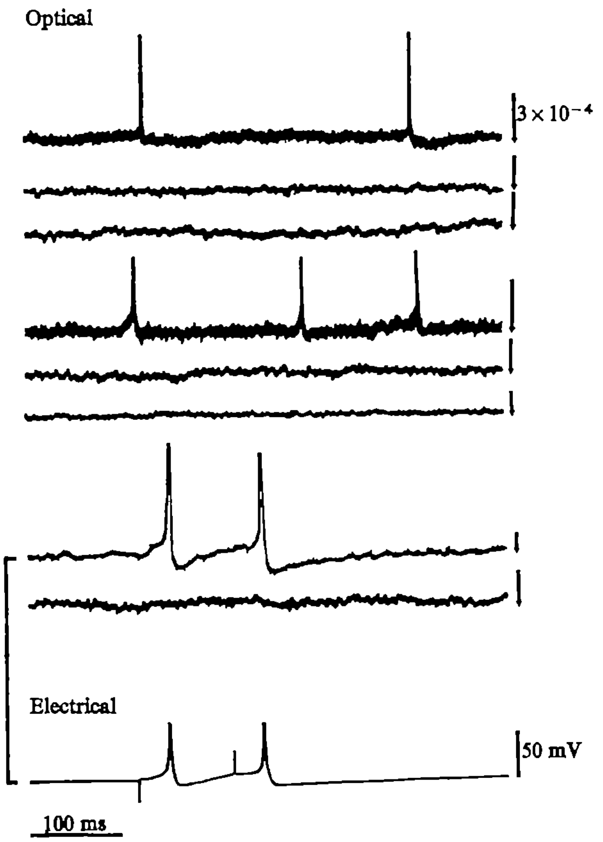

Fig. 2 Simultaneous optical recording from eight neurones. Neurone 7 was stimulated by passing current through the microelectrode; spontaneous action potentials are recorded from neurones 1 and 4. Each arrow represents a $\Delta A/A$ of 3×10^{-4}. ($\Delta I/I$, the observed fractional change in light intensity reaching the photodetector, is about half as much.)

Antagonism of ethanol narcosis by histidyl-proline diketopiperazine

THYROTROPIN-RELEASING hormone, pyroglutamyl-histidyl-prolineamide (TRH, Fig. 1) belongs to the class of hypothalamic peptides termed releasing factors[1]. Although TRH was originally described as the hormone which stimulates the release of thyrotropin, it has subsequently been shown to be involved in many other biological processes[1]. The mechanism by which TRH exhibits this broad range of activities is not clear; it might involve the action of TRH at multiple recognition sites or TRH might serve as a precursor for compounds which are biologically active. Previous studies on TRH metabolism have demonstrated the formation of pyroglutamyl-histidyl-proline (acid TRH, Fig. 1)[1]. Attempts to associate biological activity with this compound have been uniformly negative, providing no support for the precursor hypothesis[2,3]. We show here that, in addition to acid TRH, TRH is also metabolised to histidyl-proline diketopiperazine (His-Pro, Fig. 1)[4,5]. This cyclic dipeptide is substantially more potent than TRH in reducing ethanol-induced sleep in rats[6]. These data indicate that TRH metabolism plays a part in its biological effects.

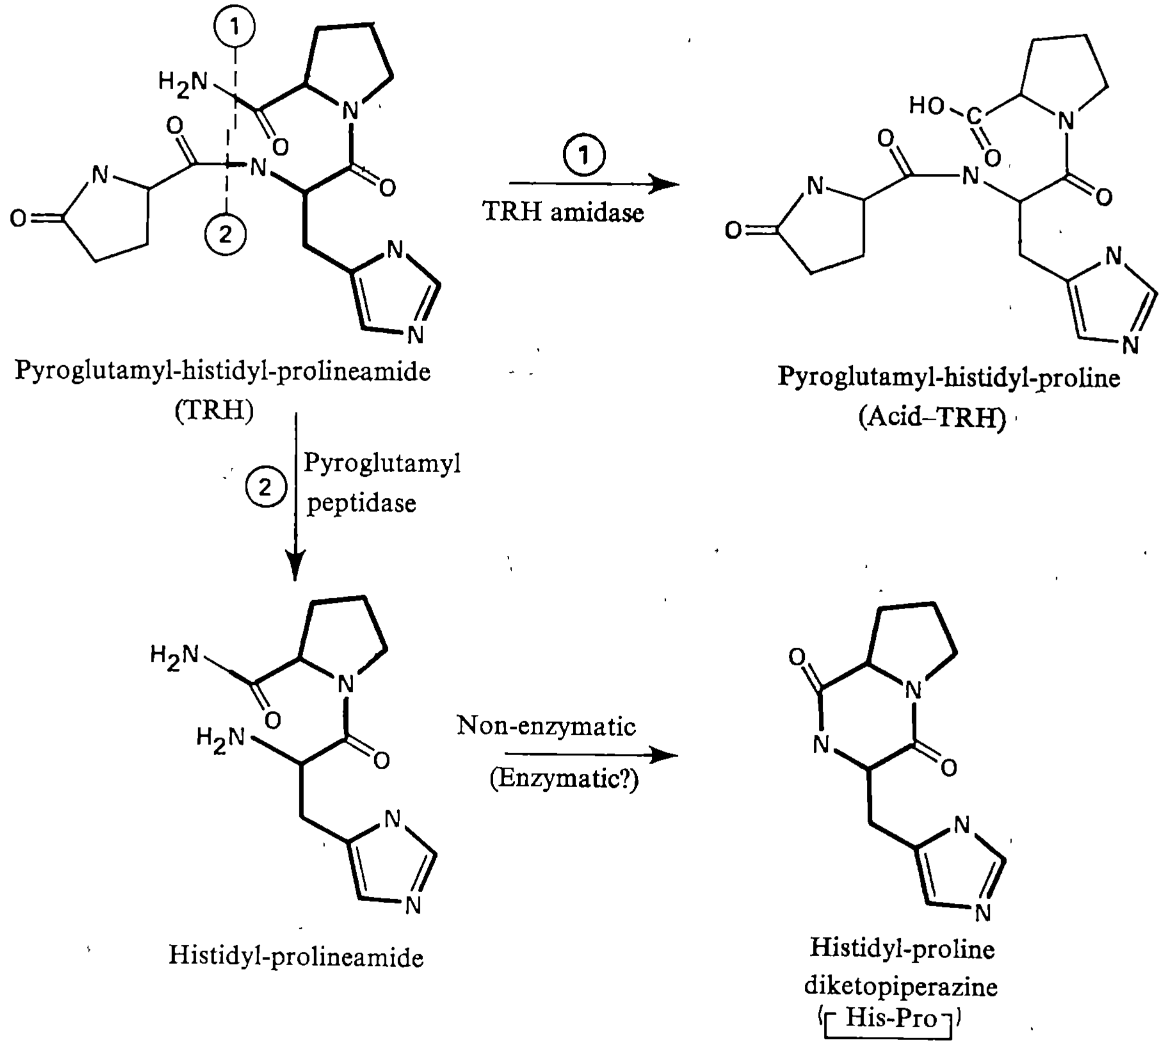

Fig. 1 Pathway of TRH metabolism in rat brain. The portion of the structure of TRH designated by the heavy lines corresponds to the region which gives rise to histidyl-prolineamide and histidyl-proline diketopiperazine. Synthetic L-histidyl-L-proline diketopiperazine was prepared by coupling benzyloxycarbonyl-L-histidine (20 mmol, ICN) with L-prolineamide (20 mmol, Vega-Fox) in the presence of hydroxybenzotriazole (40 mmol, Aldrich), *N*-ethylmorpholine (20 mmol, Aldrich) and dicyclohexylcarbodiimide (20 mmol, Pierce). The solution in 175 ml of dimethylformamide was stirred in an ice-bath for 3 h and then overnight at room temperature. After removal of the precipitated dicyclohexylurea, the solution was concentrated to dryness *in vacuo*, then dissolved in approximately 25 ml of H_2O. The solution was applied to a column (3 × 20 cm) of diethylaminoethylcellulose (Whatman DE-23, free base) previously equilibrated with H_2O and eluted with H_2O (10-ml fractions). Those fractions which were Pauly positive[10] were pooled and concentrated to dryness *in vacuo*. The intermediate benzyloxycarbonyl-L-histidyl-L-prolineamide was crystallised four times from hot H_2O (yield approximately 500 mg; microanalysis for C,H,N,O, (Microanalysis, Inc., Wilmington, Delaware), showed (in %): 58.94, 6.04, 18.04, 16.90). The calculated values are: 59.21, 6.02, 18.17, 16.60. Benzyloxycarbonyl-L-histidyl-L-prolineamide (500 mg) was dissolved in a solution containing methanol (10 ml), H_2O (0.3 ml) and glacial acetic acid (0.3 ml). After adding palladium black catalyst (100 mg), the suspension was hydrogenated under 40 pounds pressure for 2 h. The catalyst was removed by filtration and the resultant solution was heated in a boiling H_2O bath for 30 min, then dried *in vacuo* After dissolving the product in H_2O, it was purified by passage through a column (2 × 5 cm) of DEAE–cellulose; the column was washed with H_2O. The Pauly-positive fractions were concentrated to dryness *in vacuo* to yield crystalline L-histidyl-L-proline diketopiperazine (yield approximately 200 mg). Microanalysis for C,H,N,O showed (in %): 54.75, 6.08, 22.10, 17.22. The calculated values for His-Pro·0.6 H_2O are: 53.91, 6.25, 22.86, 16 97. Mass spectrographic analysis showed prominent ions at *m/e* 234 (the molecular ion of His-Pro), *m/e* 154 (the proline-glycine diketopiperazine ion), *m/e* 81 (the methyl imidazole ion) and *m/e* 70 (the pyrroline ion). ^{1}H-magnetic resonance spectral analysis at 100 MHz showed chemical shifts at 1.95, 2.2, 3.4, 3.5, 4.65, 7.4 and 8.25 p.p.m. downfield from trimethylsilane. Amino acid analysis of an acid hydrolysate (6 M HCl, 15 pounds inch^{-2}, 180 min) showed the presence of ninhydrin-positive material corresponding only to proline and histidine (ratio 1.1:1).

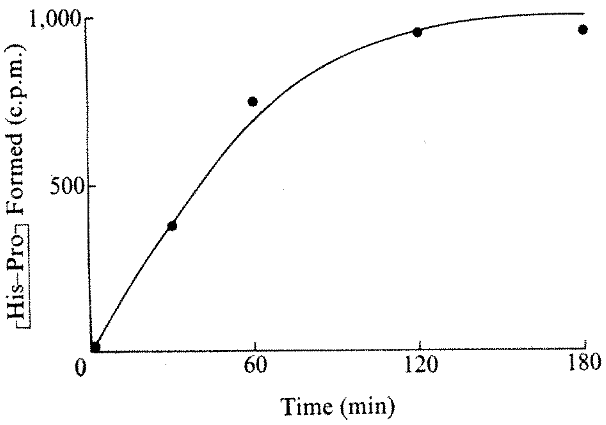

Fig. 2 Non-enzymatic formation of His-Pro from His-ProNH$_2$. [^{3}H-Pro]-His-ProNH$_2$ was prepared from [^{3}H-Pro]-TRH (New England Nuclear) as follows: 41 μmol of [^{3}H-Pro-]TRH (1.21 μCi μmol^{-1}) was incubated with 50 μmol Tris-HCl (*p*H 7.5) and 800 μl *Aerobacter cloacae* pGlu-peptidase (purified up to the Sephadex G-100 stage as described by Doolittle and Armentrout[7], activity = 0.3 μmol pGlu-Ala hydrolysed min^{-1} ml^{-1}) for 3 h at 25 °C in a total volume of 1 ml. At the end of the incubation period, the whole reaction mixture was applied to a sheet of Whatman 3 MM (60×45 cm) paper and chromatographed in 1-butanol–acetic acid–H$_2$O (4:1:1) (ascending, overnight, 25 °C). The area on the paper corresponding to His-ProNH$_2$ (R_f = 0.12–0.13, 4.7% of the total radioactivity) was cut out and extracted with 10 ml of 90% methanol. The methanol extract was filtered and concentrated *in vacuo* at 25 °C. The [^{3}H-Pro]-His-ProNH$_2$ comigrated with authentic His-ProNH$_2$ on paper chromatography (ascending, 25 °C, 15 h, Whatman 3 MM, chloroform–methanol–H$_2$O (5:5:1), (Solvent 1) R_f = 0.42) and paper electrophoresis (25 °C, Whatman 3 MM paper, 15 V cm^{-1}, 60 min, formic acid–acetic acid–H$_2$O (31:59:910), *p*H 2.0). [^{3}H-Pro]-His-ProNH$_2$ (1.9 μmol; 1.21 μCi μmol^{-1}) was incubated in PBS (200 μl) at 37 °C. At the times, indicated aliquots (20 μl) of the reaction mixture were spotted on a sheet of Whatman 3 MM paper. After overnight chromatography in solvent 1, the areas corresponding to His-Pro (R_f = 0.73) were cut out and counted in a liquid scintillation counter.

Our work has demonstrated the presence in extracts of hamster hypothalamus[4] and rat brain (unpublished observations) of the enzyme pyroglutamylpeptidase (L-pyroglutamyl peptide hydrolase, EC 3.4.11.8) which converts TRH to histidyl-prolineamide. This metabolite is unstable and readily cyclises to histidyl-proline diketopiperazine (His-Pro) (Fig. 1). The data in Fig. 2 document the instability of histidyl-prolineamide in phosphate buffered saline (PBS; 0.1 M potassium phosphate + 0.14 M NaCl, *p*H 7.2). ^{3}H-proline-histidyl-prolineamide was prepared by incubation of ^{3}H-proline-TRH with partially purified bacterial pyroglutamyl-peptidase[7]. Incubation of ^{3}H-proline-histidyl-prolineamide at 37 °C in PBS resulted in rapid cyclisation to the diketopiperazine. The half life of histidyl-prolineamide in these conditions was approximately 40 min. These data suggest that the pyroglutamylpeptidase-dependent conversion of TRH in brain to histidyl-prolineamide is probably followed by a rapid cyclisation to His-Pro.

The results of a further study (Fig. 3) provided additional evidence that His-Pro is an *in vivo* metabolite of TRH. [^{3}H-Proline]-TRH (20 μl) was injected into the right lateral ventricle of a rat[8]. The animal was decapitated 5 min after the injection; the brain was then removed and extracted with 10 ml of 0.4 N HClO$_4$. Paper chromatography of the neutralised HClO$_4$ extract (see legend Fig. 3) revealed that, in addition to residual TRH, radioactivity was localised in acid TRH,, linear histidyl-proline and His-Pro (approximately 8% of the total radioactivity). Incubation of acid-inactivated brain with radioactive TRH, followed by the same extraction procedure, indicated that TRH was not degraded non-enzymatically. The linear histidyl-proline was probably either derived from acid TRH by the action of pyroglutamylpeptidase or from histidyl-prolineamide by the action of TRH amidase[4]. The scheme shown in Fig. 1 summarises our present theory on the pathway for TRH metabolism in brain. We have established the existence of enzymes forming acid TRH and histidyl-prolineamide[4]. Although the existence of an enzyme catalysing the conversion of histidyl-prolineamide to His-Pro seems likely, the instability of histidyl-prolineamide has, thus far, hindered out attempts to detect such an activity.

Breese *et al.*[6,9] reported that TRH antagonises the effect of ethanol in inducing sleep in mice and rats; acid TRH did not substitute for TRH in this reduction of ethanol narcosis. Our findings that His-Pro is another metabolic of TRH prompted us to test its effect on ethanol narcosis. Figure 4 shows concentration curves for effectiveness of TRH and His-Pro in reducing ethanol-induced sleep. The data confirm the finding[6,9] that TRH antagonises ethanol narcosis and that acid TRH is inactive. There was no effect on the time for loss of the righting reflex, but TRH significantly decreased the righting time. The more important finding, however, is that His-Pro is substantially more effective than TRH in this test. The data suggest that a reduction of sleep time to 50% of the control requires intraventricular injection of 1 μmol kg^{-1} of His-Pro or 50 μmol kg^{-1} of TRH The study shown in Fig. 3 indicated that the intraventricular injection of 1 μmol kg^{-1} of TRH leads to the formation of approximately 0.08 μmol kg^{-1} of His-Pro. Figure 4 shows that 1 μmol kg^{-1} of TRH or 0.08 μmol kg^{-1} of His-Pro produce comparable reductions in ethanol-induced sleep. This observation is compatible with the notion that the activity of TRH in antagonising ethanol narcosis requires its conversion to His-Pro.

We previously introduced the hypothesis that the metabolism of TRH may generate compounds with biological

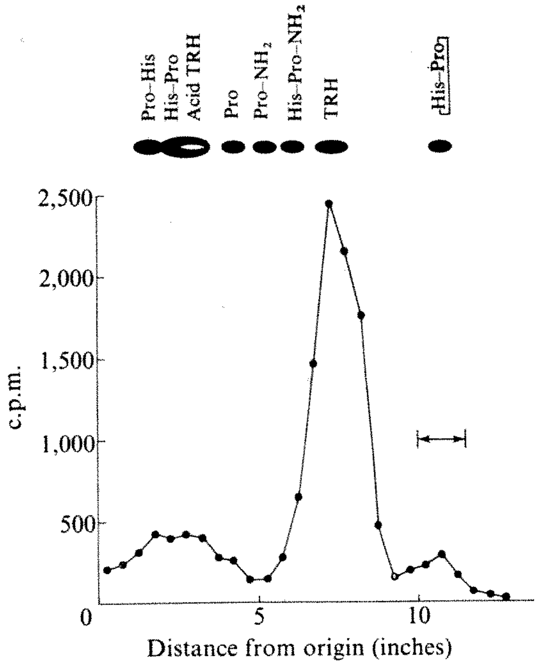

Fig. 3 Formation of His-Pro from intraventricularly administered TRH. A male Sprague-Dawley rat (approximately 100 g) was injected with 20 μl [^{3}H-Pro]-TRH (10 μc, 100 μCi μmol^{-1}) in saline. The animal was decapitated 5 min after injection, and the brain quickly removed. The brain was homogenised in 0.4 N HClO$_4$ (10 ml) and the centrifuged extract adjusted to *p*H 6.4–6.6 with saturated KHCO$_3$ solution. The supernatant solution was lyophilised and then extracted with a small volume of 90% methanol. The methanol extract was applied in a 30-cm band to a sheet of Whatman 3 MM paper and chromatographed (ascending) in solvent 1. The chromatogram was dried and a 1-inch strip was cut into 0.5 inch segments and counted. The area corresponding to His-Pro (10–11.5 inches from the origin) was extracted with methanol and rechromatographed (ascending) in chloroform–methanol–NH$_4$OH (60:45:20). The radioactivity comigrated with authentic His-Pro (R_f = 0.73).

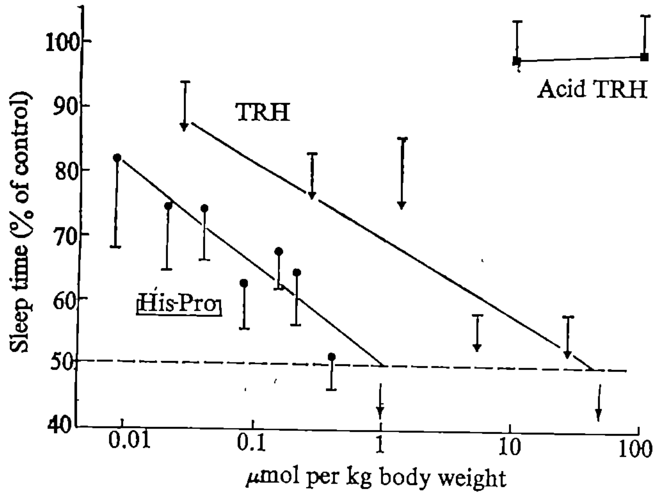

Fig. 4 Effect of TRH and His-Pro on sleep induced by ethanol. All animals were injected intraperitoneally with 8 ml ethanol (50% v/v in saline) per kg body weight. TRH, acid TRH or His-Pro (dissolved in saline) were administered to rats intraventricularly (15–18 μl per animal) under light ether anaesthesia 10 min before the ethanol injection. The concentrations of the peptide solutions were such that 100 μl contained the indicated number of μmol. Sleeping time for animals was determined as described earlier[6]. The sleep time for control animals receiving saline intraventricularly and ethanol intraperitoneally was 69±8 min ($n = 17$). Each point represents 6–10 animals (150–180 g) and the data are presented as mean±s.e.m. The horizontal dashed line corresponds to a 50% decrease in the sleep time. The arrows point to the concentrations of His-Pro and TRH required to effect a 50% decrease in the sleep time induced by ethanol.

activity[4] and the data presented here validate this idea. It will be of interest to see whether His-Pro corresponds to the 'active' form of TRH in a number of other systems where TRH has shown effects. It seems unlikely that TRH metabolism is obligatory for all of its effects since neither acid TRH nor His-Pro can replace TRH in reducing pentobarbital-induced sleep (preliminary experiments). Thus, the complete role of His-Pro in 'TRH-mediated' functions remains to be established.

We thank Dr John Folk of the National Institute of Dental Research for his assistance in the catalytic hydrogenation of the benzyloxycarbonyl-L-histidyl-L-prolineamide and Drs Henry Fales and Robert Highet of the National Heart, Lung, and Blood Institute for mass spectrographic and proton magnetic resonance analysis of histidyl-proline diketopiperazine, respectively. Amino acid analysis of His-Pro was performed by Drs K. A. Piez and J. Schrode of the National Institute for Dental Research. Drs A. O. Geiszler of Abbott Laboratories and Arthur Felix of Hoffman-La Roche, Nutley, New Jersey, provided histidyl-prolineamide and acid TRH, respectively. We thank Drs A. Guarino, W. Klee, G. Maloney, E. P. Noble, J. Orloff, B. Peterkofsky, J. E. Rall, L. Sokoloff and J. Walters for their helpful comments on the paper.

Eighty thousand β-adrenoreceptors in a single cell

CATECHOLAMINES function as hormones in peripheral organs and as neurotransmitters in the central nervous system (CNS). The primary event in the action of catecholamines is their interaction with specific α-adrenoreceptors or β-adrenoreceptors[1]. The interaction of catecholamines with β-adrenoreceptors induces the activation of the enzyme adenylate cyclase which converts adenosine triphosphate (ATP) to cyclic AMP (ref. 2). Development of reliable radioligand binding methods has enabled the direct determination of the number of β-adrenoreceptors in various cell types[3–13]. The content of β-adrenoreceptors in all the cells examined varies between a few hundred and a few thousand receptors per cell. These values correspond to $(0.2–2.0)\times10^{-12}$ mol receptor per mg membrane protein, when membranes are prepared from these cells.

The absence of a rich source for β-adrenoreceptors had hindered attempts to identify and purify the receptor molecule. A report by Schubert *et al.*[13] showed that skeletal muscle myoblasts (L6 cells) grown in culture respond to (−) noradrenaline by a 500-fold increase in their intracellular content of cyclic AMP and this finding prompted us to examine the β-adrenoreceptor density of these cells. We report here on the presence of 80,000 β-adrenoreceptors per cell in L6P cells grown in culture, as determined by a direct binding of ^{125}I-(±)-iodohydroxybenzylpindolol (^{125}I-(±)-HYP) to intact cells. In parallel, we examined the direct binding method by measuring ^{125}I-(±)-HYP binding to intact turkey erythrocytes.

Rat skeletal myoblasts polyploid cells[14] (L6P) were obtained from Dr D. Yaffe. The cells grown on collagen were detached from their support by incubation with ethylene diamine tetraacetate (EDTA) 1.5 mM for 2 h, washed and suspended in the isotonic buffer and ^{125}I-(±)-HYP binding was measured. The experimental details are given in Fig. 1. The binding of ^{125}I-(±)-HYP to intact turkey erythrocytes was also measured (Fig. 2) using similar conditions. Both L6P cells and turkey erythrocytes demonstrate a single class of ^{125}I-(±)-HYP binding sites (Figs 1*c* and 2*c*) and exhibit the same affinity towards the radiolabelled β-blocker (Figs 1 and 2 and Table 1).

L6P cells were found to possess 80,000 ^{125}I-(±)-HYP

Table 1 Number of β-adrenoreceptors in intact L6P cells and intact turkey erythrocytes

Cell type	Number of ^{125}I-(±)-HYP binding sites per cell	^{125}I-(±)-HYP receptor dissociation constant (M)	Ref.
L6P	80,000	1.74×10^{-10}	This study
Turkey erythrocytes*	1,100	1.60×10^{-10}	This study
Turkey erythrocytes	400–500	1.9×10^{-11}	12

* Turkey erythrocyte membranes were found to have 0.9 pmol receptor per mg membrane protein, using ^{3}H-(±)-propranolol binding[3, 4]. On the basis of this finding it was calculated that an intact turkey erythrocyte has 550±120 receptors per cell[3]. Using equilibrium dialysis with ^{3}H-(±)-isoproterenol, the number of specific β-adrenoreceptors was found to be 1,200±300 receptors per cell[3].

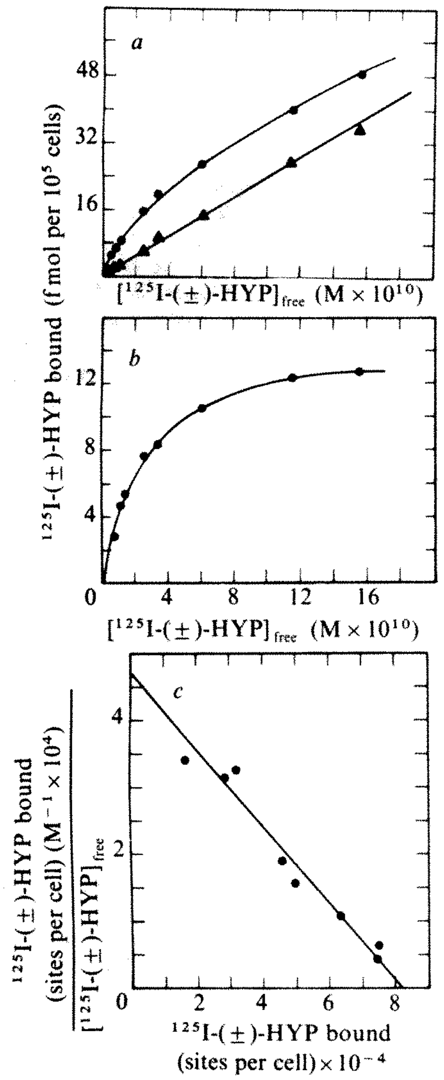

Fig. 1 Binding of ^{125}I-(±)-HYP to intact L6P cells. ^{125}I-(±)-HYP was prepared and purified as described previously[9] and L6P skeletal muscle myoblasts were grown in plastic bottles for 9 d as described[14]. To detach the cells, the growth medium was removed and the clone incubated with 10 mM Tris-HCl *p*H 7.4 containing 1.5 mM Na_2EDTA and 140 mM NaCl at 37 °C for 2 h. The surface was then scraped gently with a rubber stick to detach the cells from the surface. On exposure to the detaching buffer, the cells became round within 15 min as viewed under the microscope. The suspended cells were then centrifuged for 5 min at 950*g* and the washed cells were resuspended in 1.2 ml of the above buffer, counted and used for the ^{125}I-(±)-HYP binding assay. Fifty microlitres containing 1.0×10^5 cells ml^{-1} or 1.0×10^6 cells ml^{-1} were mixed with 0.45 ml of the buffer which contained increasing concentrations of ^{125}I-(±)-HYP ($0.2–15.6 \times 10^{-10}$ M) in the absence and in the presence of DL-propranolol (5.0×10^{-5} M final concentration). Thus the final concentration of cells in the binding mixture was 1.0×10^4 cells ml^{-1} in one set and 1.0×10^5 cells ml^{-1} in the second set. The binding mixtures were incubated for 30 min at 37 °C. Subsequently 0.45 ml of each binding mixture was filtered on a Whatman GF/C glass filter as previously described[9, 12] and counted in a gamma counter (Packard). A sample of 50 µl from each binding mixture was counted to determine the total ^{125}I-(±)-HYP concentration. From the values obtained for the bound ^{125}I-(±)-HYP and the total ^{125}I-(±)-HYP concentration in the binding mixture, the values of [^{125}I-HYP]$_{free}$ were computed. Each point represents the mean of two determinations. The data presented are for 1.0×10^5 cells ml^{-1} final concentration in the binding assay. *a*, Total ^{125}I-(±)-HYP bound; ▲, ^{125}I-(±)-HYP bound in the presence of 5.0×10^{-5} DL-propranolol (nonspecific binding). *b*, Specific ^{125}I-(±)-HYP bound. *c*, Scatchard plot of data in *b*. The data in *b* were converted from fmol per 10^5 cells to number of receptors per cell. Maximal binding was found to be 13.4 fmol ^{125}I-(±)-HYP per 10^5 cells ($13.4 \times 6.03 \times 10^{23} \times 10^{-15}$ ^{125}I-(±)-HYP sites per 10^5 cells, which equals 80,400 receptors per cell; 6.03×10^{23} is Avogadro's number). Analysis of binding using 10^4 cells ml^{-1} yields 81,200 receptors per cell.

binding sites (Fig. 1), whereas turkey erythrocytes were found to possess 1,100 (Fig. 2). The latter value is close to the number of β-adrenoreceptors calculated on the basis of ^{3}H-(±)-propranolol binding to turkey erythrocyte membranes and to the value reported by Brown *et al.*[12], who measured ^{125}I-(±)-HYP binding to intact turkey erythrocytes (Table 1). The binding of ^{125}I-(±)-HYP in both cell types is inhibited by (±)-propranolol (Figs 1 and 2), a specific β-adrenergic blocker, and is completed within 20 min of incubation. The maximal capacity of ^{125}I-(±)-HYP binding was found to be directly proportional to the cell concentration in the range of 10^4 cells ml^{-1} to 5×10^5 cells ml^{-1} for L6P cells, and in the range 1.0×10^6 to 5.0×10^7 cells ml^{-1} for turkey erythrocytes, confirming that equilibrium was reached between the cells and the radiolabelled ligand within the incubation time used.

In conclusion, it seems that the L6P cell line can become

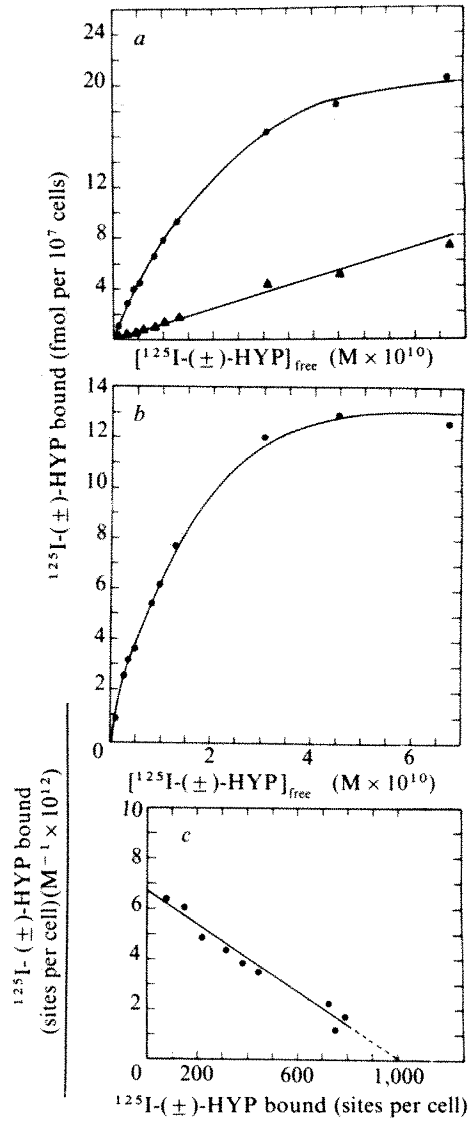

Fig. 2 Binding of ^{125}I-(±)-HYP to intact turkey erythrocytes. The preparation of a cell suspension of turkey erythrocytes essentially followed a published procedure[12, 15]. Fresh heparinised blood from adult turkeys was centrifuged at 400*g* for 10 min at 4 °C. This step was repeated four times. The washed erythrocytes were resuspended in 10 mM Tris-HCl *p*H 7.4 containing 0.14 M NaCl, 10 mM KCl, 11 mM glucose and 50 units ml^{-1} penicillin. A final concentration of 1.0×10^6 cells ml^{-1} and of 1.0×10^7 cells ml^{-1} were used for the binding experiments. The following steps were identical to those described in the legend to Figure 1. *a*, Total ^{125}I-(±)-HYP bound; ▲, ^{125}I-(±)-HYP bound in the presence of 5.0×10^{-5} M (±)-propranolol. *b*, Specific ^{125}I-(±)-HYP bound. *c*, Scatchard plot of data in *b*.

a good candidate for a rich source of β-adrenoreceptors. The access to such a source may advance the efforts aimed at the chemical characterisation of the β-adrenoreceptor and possibly its purification.

We thank Dr David Yaffe and Ms Ruth Meller from the Weizmann Institute, Rehovot, for the L6P cells and for their invaluable advice. We also thank Dr V. I. Teichberg from the Institut Pasteur, Paris, for stimulating discussions. How motoneurones control development of muscle tension

THE sum of all synaptic currents flowing at any moment through the motoneurone membrane represents the synthesis of the commands converging on to the final common path. Transduction of such commands into muscle contraction is accomplished by the conversion of current into motoneuronal firing and, in turn, conversion of the nervous discharge into mechanical events[1]. Thus, the motor unit, that is, each motoneurone with the muscle fibres it innervates, operates as the interface between the central nervous system and the environment. The motor unit response to steady inputs is well known. Constant currents are transformed into constant-rate discharges, whose frequencies are proportional, over a definite range, to the current intensities[2]; in isometric conditions, such constant-rate discharges build up steady and proportional levels of muscle tension[3-6]. On the other hand, little is known about the motor unit response to dynamic inputs. Recent work[5], however, has suggested that the rate of growth of the current stimulating the motoneurone may be converted into a proportional rate of development of the muscle tension. In view of this last hypothesis, we have analysed the isometric tension developed by single motor units when motoneurones were stimulated with current pulses of trapezoidal shape, that is, reaching a given steady level after rectilineal (ramp) growth of different slopes. This approach was adopted on the assumption that current injected by an intracellular electrode into a motoneurone is physically equivalent of total synaptic current acting on the cell[1,2].

In cats the spinal cord was transected at high cervical level under sodium pentobarbital anaesthesia (40 mg per kg body weight), the lumbar cord was exposed and the tendon of the gastrocnemius-soleus (G–S) muscle cut and attached to an isometric force transducer (Grass FT03). The muscle was stretched and maintained at the length giving the maximal isometric twitch response. The activity of G–S motoneurones was recorded intracellularly using glass microelectrodes (3 M KCl) through which depolarising current pulses of trapezoidal shape (total duration 200–250 ms) were passed across the cell membrane. The rising phase of the pulses was rectilineal and the rise-time variable between 0 (rectangular pulse) and 120 ms. In some experiments, the trapezoidal currents were superimposed on a current step of rheobasic intensity. This experimental procedure has been successfully completed in nine motor units, all belonging to the fast type[6] (time-to-peak of the single twitch: 18–25 ms). In eight of the nine the trials could be repeated for several different values of the steady-state current. Shape of the current pulses, motoneuronal discharge and isometric tension developed by the motor units were simultaneously displayed on the oscilloscope and photographed.

Constant-rate firing of a motoneurone can be obtained by two different methods, each leading to a different mode of muscle tension development. The motoneuronal discharge may be obtained by a train of individual short current pulses, each eliciting a single spike (Fig. 1*a*). Alternatively, rhythmic firing can be evoked by a long-lasting rectangular current step (Fig. 1*b*): in this case a constant-rate discharge of the same frequency as in Fig. 1*a* is reached through adaptation, that is, after the fall of the high instantaneous frequency of the first interspike interval. Such a frequency reduction is caused by summation of the conductance changes underlying the spike's afterhyperpolarisation (AHP) (refs 7–11). The related tension recordings show that muscular response is much faster and stronger in (*b*) than in (*a*). In (*b*) firing attains the same frequency as in (*a*) just after the second spike: the difference in tension seems therefore to be attributable to the initial, non-adapted, high-frequency discharge produced by the rectangular current. This suggests that modulation of the high-frequency, non-

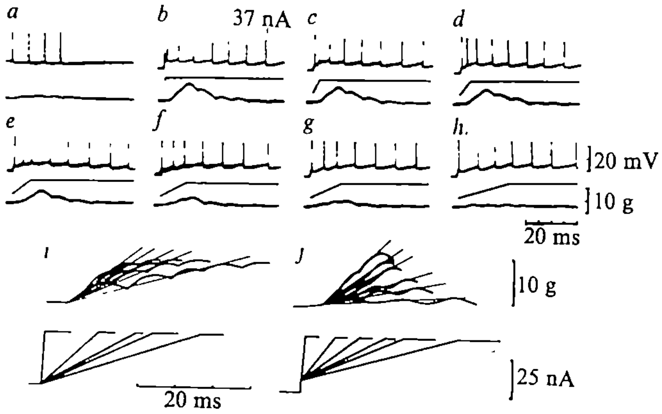

Fig. 1 Response of a motor unit to rectilineal input transients of different slopes. *b–h*, G–S motor unit of the fast type (time to peak for the single twitch 20 ms). For each recording, the middle trace represents the time-course of the motoneurone-stimulating current, the uppermost the neuronal discharge, the lowermost the mechanical response. Decrease in the slope of the current rising phase is accompanied by a parallel decrease in the peak initial tension and in the velocity of tension development. This is mediated by a rearrangement of the early phase of motoneurone firing, whose major feature is a progressive lengthening of the first interspike interval. With the slowest-rising ramp (*h*), firing frequency is nearly regular from the very beginning. Profile of isometric tension is, in this trial, similar to that obtained by single-pulse, constant-rate stimulation of motor cell (*a*). *i*, *j*, Upper traces are superimposed drawings of the tension profiles recorded in the same unit (*i*) and in another (*j*) fast G–S unit (single twitch time-to peak 25 ms) in which the amplitude of peak initial tension was not affected by the slope of stimulating current (lower traces). Straight lines connect the onset of tension with the points where 90% of peak tension is reached in each trial.

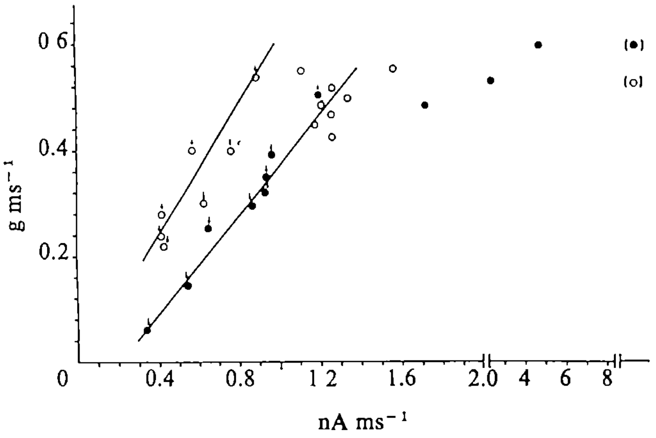

Fig. 2 Correlations between velocity of current commands to motoneurones and velocity of muscle tension recruitment Same units as in Fig. 1*j* (○) and *i* (●). Abscissa: velocity of the rising phase of the currents injected into the motoneurones in nA ms^{-1}. Ordinate: velocity of development of isometric tension, calculated as the slope of the straight lines drawn in Fig. 1 *i* and *j*. Points within brackets (on the right) signal the tension velocity developed by a rectangular pulse. Straight lines represent the regression functions calculated by the least squares method from the points marked by arrows. Note scale changes on abscissa.

adapted discharge may lead to a correlated modulation of the initial, transient phase of the tension profile.

The same motor unit was then stimulated with trapezoidal current pulses reaching the same level as in Fig. 1*b*, but after ramps of different slopes. Figure 1 *c–h* shows that decreasing the ramp slope has a clear-cut effect on the initial part of the motoneuronal discharge but leaves steady-state firing untouched. The effect consists of a progressive increase in duration of the first interspike interval while the second and eventually (Fig. 1*h*) the third intervals undergo more complex changes. The relationships between changes in the ramp slope and rearrangement of the motoneuronal initial discharge will be analysed in detail elsewhere. It is of value here to follow the manner in which such slope changes modify the tension profiles. Figure 1 *c–h* shows that a slowing down of the current rising phase is paralleled by a proportional reduction of both the absolute value of muscle tension and of its slope. This is more apparent in Fig. 1*j*, where the tension profiles from six records are superimposed.

Velocity of tension development was estimated from the experimental records by calculating the slope of the straight lines connecting the tension onset to the point at which 90% of maximal force was attained in each trial (Fig. 1*j*). This velocity has been plotted against the rise velocity of the related currents, as illustrated by the filled circles in Fig. 2. It is evident here that the two velocities are directly related to each other. Correlation seems to be linear over a considerable range of values, from about 0.3 nA ms^{-1} up to 1.2 nA ms^{-1}. Ramps steeper than 1.2 nA ms^{-1} do not increase the velocity of tension development much further (maximal velocity, attained with the rectangular current step, is represented by the dot within brackets). Such an insensitivity to the highest ramp slopes can be directly appreciated by comparing records (*c*) and (*b*) in Fig. 1.

In this motor unit, as well as in four other units in the present material (see also refs 5 and 12), tension responses to fast transients display an initial peak whose amplitude is positively correlated with ramp velocity (Fig. 1 *c–h*). Such a peak might be important in non-isometric conditions, when an initial extra force may be required for quickly overcoming inertia at the start of the movement. In these units, the behaviour described above was less evident, or even disappeared, when the strength of the current pulse was increased: this produced a proportional increase of steady-state firing rate, which eventually became sufficiently high to keep the tension at (or close to) the level reached initially. Figure 1*i* refers to the response encountered in the remaining four units and represents a series of tension profiles obtained from one of them and superimposed as in Fig. 1*j*. These profiles do not show any initial peak: whatever the strength of the current pulse, motoneuronal firing frequency at steady state (not illustrated) was always high enough to prevent the tension from falling after adaptation. In this unit, variations of the ramp slope are accompanied only by proportional changes in the slope of tension development. Velocity plot (Fig. 2, open circles) displays the same type of correlation described in the preceding example. This correlation was also consistently found in all other units investigated, independently of the presence or absence of the initial tension peak.

The linear transduction of the velocity of transients demonstrated here seems to depend on special properties of both components of the motor unit. Motoneurones encode velocity of the rising phase of a trapezoidal input signal by modulating the frequency of their initial, non-adapted discharge. The firing response to a current step represents the borderline example of such a modulation. It is accepted that the changes in firing frequency (that is, adaptation) observable in that condition are caused by the kinetics of summation of the AHP conductance changes[10,13,14]. It therefore seems justifiable to assume that the same mechanism is also responsible for the modulation of motoneuronal discharge in response to ramps of different slopes.

At the muscular level, a feature which should prominently contribute to regulation of the rate of tension recruitment are the so called 'catch properties'[15], that is, the strong 'potentiation' of the muscle twitch following the second of two short-interval stimuli[15,16].

It can be concluded that the motor unit is provided with a mechanism for independent transduction of both the steady levels and the transients of the input signals. While the steady level of isometric tension is proportional to the steady intensity of the current command to the motoneurone, velocity of force development can be regulated (over a definite range limited by the intrinsic muscle properties) by the command slope.

Acetylcholine-like effects of intracellular calcium application in pancreatic acinar cells

INDIRECT evidence suggests that Ca^{2+} is the mediator of the effects of acetylcholine and cholecystokinin-pancreozymin in pancreatic acinar cells. Sustained stimulation-evoked acinar fluid and enzyme secretion depends on extracellular Ca^{2+} (refs 1,2), stimulation causes uptake of ^{45}Ca^{2+} from the extracellular fluid[3] as well as release of ^{45}Ca^{2+} from prelabelled glands with a dose–response curve very similar to stimulation-evoked membrane depolarisation and enzyme secretion[4] and the Ca^{2+} ionophore A23187 induces enzyme secretion[5] and membrane depolarisation[6]. We have examined directly the bioelectrical effects of iontophoretic application of Ca^{2+} from intracellular microelectrodes in a mammalian gland cell preparation.

Two separate microelectrodes, one filled with either 0.2 M CaCl$_2$ (or sometimes 0.2 M MgCl$_2$) plus 0.05 M EGTA (ethylene glycol-*bis*-β (amino-ethylether)-*N*,*N'*-tetraacetic acid) (*p*H 7) or 3 M KCl and the other always filled with 3M KCl, were inserted very close to each other (20–50 μm intertip distance) into communicating surface acinar cells of mouse pancreas superfused *in vitro*. The tip of a third microelectrode, filled with 2M AChCl, was placed close to the impaled acinus in an extracellular position. The magnitude of iontophoretic currents was measured using a virtual ground current–voltage converter. Apart from one of the intracellular electrodes most often containing CaCl$_2$, the set-up was identical to that used to determine the ACh null potential in pancreatic acinar cells[7]. The composition of the physiological saline solution flowing through the tissue bath was (mM): NaCl, 103; KCl, 4.7; CaCl$_2$, 2.56; MgCl$_2$, 1.13; NaHCO$_3$, 25; NaH$_2$PO$_4$, 1.15; D-glucose, 2.8; Na pyruvate, 4.9; Na glutamate, 4.9; Na fumarate, 2.7. The solution was gassed with 95% O$_2$, 5% CO$_2$.

Figure 1 shows the effects of extracellular ACh and intracellular Ca^{2+} applications in the same acinus. The effects of Ca^{2+} closely mimicked those of ACh causing membrane depolarisation, reduction of input resistance and reduction of membrane time constant. Such ACh-like effects of intracellular Ca^{2+} applications (2–20 nA, 500 ms depolarising pulses) were repeatedly obtained in 14 cells from eight glands. Hyperpolarising current pulses of this magnitude had no effect.

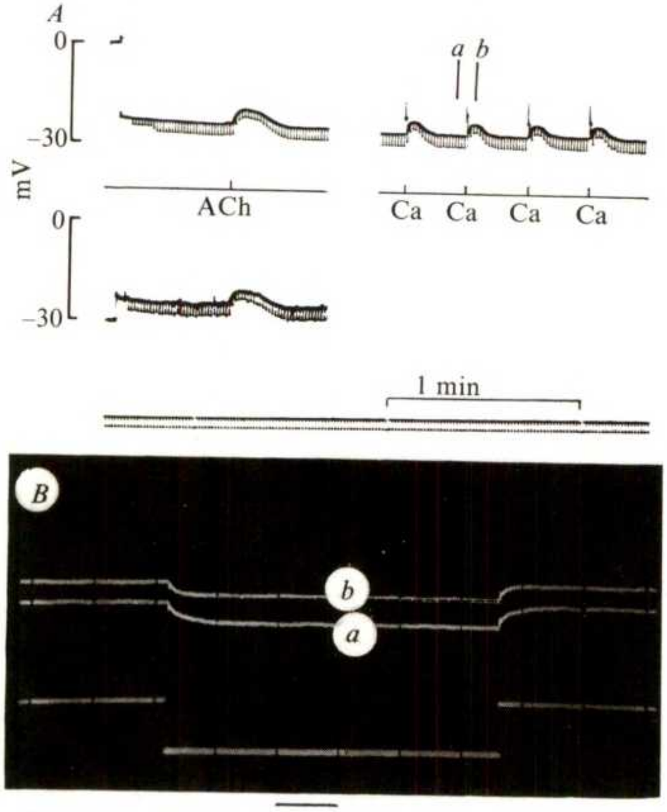

Fig. 1 The action of extracellular ACh and intracellular Ca^{2+} on membrane potential and resistance. *A*, The left-hand side of the trace shows the effect of a short pulse of iontophoretic ACh application (6×10^{-8} A, 0.5 s, retaining current 2×10^{-8} A) on membrane potential and resistance in two electrically coupled acinar cells. The upper trace represents the potential measured by an intracellular KCl electrode through which hyperpolarising rectangular current pulses (2×10^{-9} A, 100 ms duration) were injected repeatedly. The lower trace represents the membrane potential of a neighbouring cell recorded with a CaCl$_2$ electrode. At the point of interruption of the tracings, the CaCl$_2$ electrode was disconnected from the recording system and connected to a stimulator so that current could be injected through the electrode. At the marker signals labelled Ca, 5 nA, 0.5-s depolarising current pulses were applied through the Ca^{2+} electrode. *B*, The time course of membrane polarisation caused by injecting the 100-ms current pulse through the KCl electrode before and after the intracellular Ca^{2+} application (calibration: horizontal 20 ms, vertical 10 mV and 2×10^{-9} A).

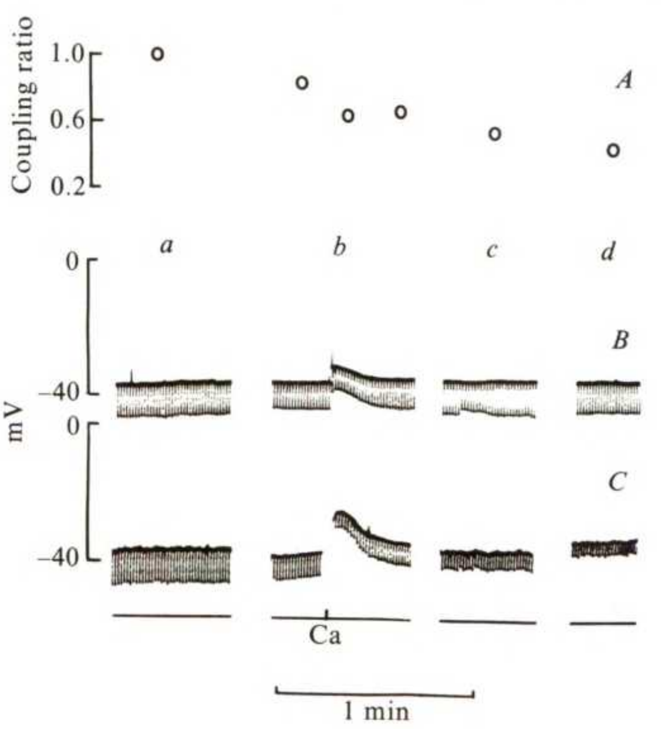

Fig. 2 The effect of repeated iontophoretic Ca^{2+} injections on acinar cell-to-cell coupling, membrane potential and resistance. *a–d*, Consecutive traces obtained from the same acinus with two indwelling electrodes in neighbouring communicating cells. *C*, Membrane potential measured by the CaCl$_2$-filled microelectrode. Iontophoretic ejections of Ca^{2+} (20 nA, 500 ms duration) were repeatedly carried out (for example section *b*). Between *a* and *b* (2.5 min interval) three such Ca^{2+} ejections occurred, between *b* and *c* (1 min interval) two ejections took place and between *c* and *d* (1.5 min interval) one ejection was made. *B*, Membrane potential measured by the KCl microelectrode. Through this electrode, current pulses (hyperpolarising, 2.5 nA, 100 ms duration) were passed repetitively. *A*, Coupling ratios (magnitude of electrotonic potential change in cell impaled by CaCl$_2$ electrode, caused by the hyperpolarising pulses injected through the KCl electrode, divided by the magnitude of the current pulse induced potential change in the cell impaled by the KCl electrode) corresponding to the situations in *a–d*.

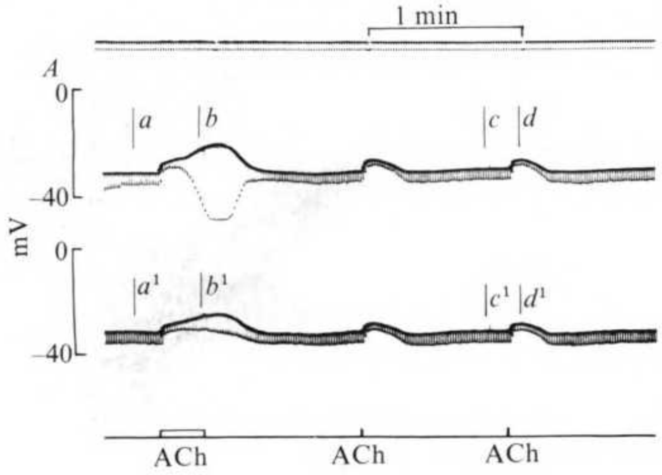
Control experiments were carried out to exclude the possibility that these effects were unrelated to the intracellular Ca^{2+} application. The effects were not caused by the current passage or the potential change, since 2–20 nA depolarising or hyperpolarising current pulses applied through a KCl electrode never had any effect (six glands). Considerably larger current pulses (50–100 nA), however, caused membrane depolarisation and resistance reduction. These effects were observed after both depolarising and hyperpolarising current pulses, but the hyperpolarising pulses were by far the more effective. The shape of these potential changes was very different from those caused by Ca^{2+} injections. The depolarising phase was much steeper and the depolarisations were more short-lived, except in the case of the largest currents (> 100 nA). This phenomenon is probably caused by a reversible dielectric breakdown in the cell membrane (refs 8 and 9 and refs therein). The effects of Ca^{2+} injections were not evoked by releasing ACh from postsynaptic nerve endings surrounding the acini, since Ca^{2+} ejections with the CaCl$_2$ electrode extracellularly had no effect, probably reflecting the paucity of 'close' innervation[10] and since the effects of intracellular Ca^{2+} applications were also observed during exposure of the gland cells to 1.4×10^{-6} M atropine (three glands) a concentration abolishing the effects of extracellular



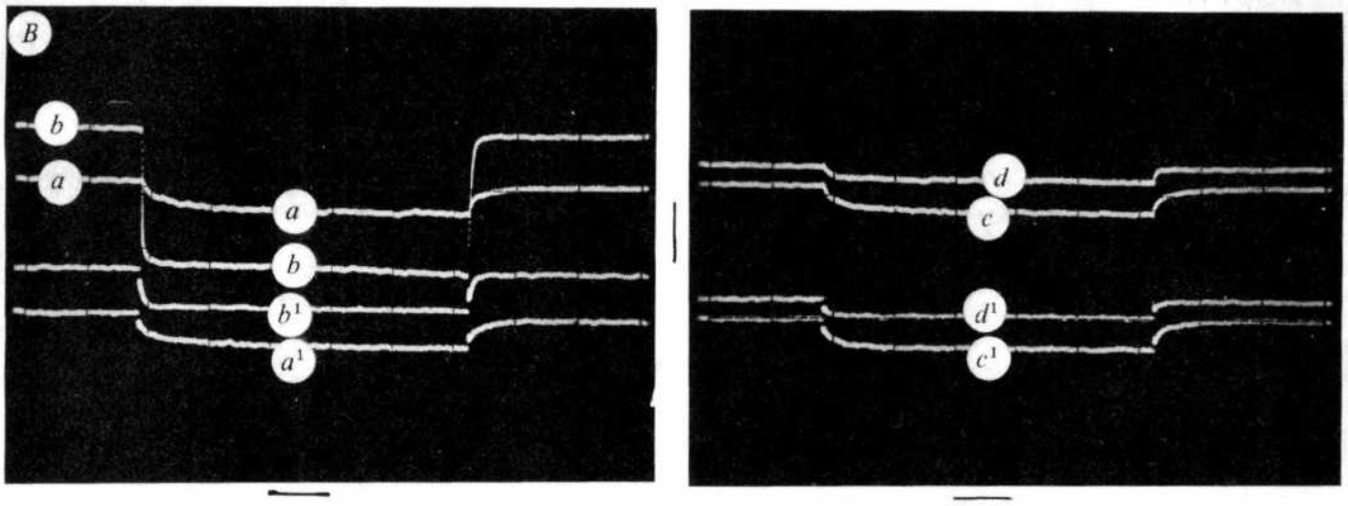


Fig. 3 The action of short and long pulses of ACh on membrane potential, resistance and electrical coupling. *A*, Two tracings of membrane potentials from two neighbouring acinar cells, both recorded with KCl electrodes. Hyperpolarising rectangular current pulses (2 × 10^{-9} A, 100 ms) were repetitively injected through the electrode recording the potential represented by the upper trace. The event marker signals represent the duration of the ejecting ACh pulses from the third extracellular microelectrode (6 × 10^{-8} A, retaining current 2 × 10^{-8} A). *B*, The shape and time course of the membrane polarisations in both cells caused by the current injections (calibration: horizontal 20 ms, vertical 10 mV).

iontophoretic ACh stimulation. The results of Ca^{2+} injections were not unspecific divalent cation effects since 2–20 nA, 500 ms depolarising current pulses applied through MgCl$_2$-filled electrodes (four glands) never caused any changes. Dielectric breakdown was observed after large current pulses (50–100 nA, both depolarising and hyperpolarising).

It is well known that intracellular Ca^{2+} injections can cause uncoupling of epithelial cells which are normally fully electrically coupled[11]. Small short-lived Ca^{2+} pulses resulting in the potential and resistance changes seen in Fig. 1 did not cause uncoupling. It was not possible to use much larger pulses since these evoked dielectric breakdown. After 5–10 min of repetitive Ca^{2+} injections in six glands, however, when it was still possible to get reliable recordings from the CaCl$_2$ electrode, uncoupling (that is, a reduction in the magnitude of electrotonic potential changes picked up by the CaCl$_2$ electrode caused by current injection through the KCl electrode in the neighbouring cell) was observed (Fig. 2). Uncoupling was never observed after Mg^{2+} or K$^+$ ejections.

The demonstration that intracellular Ca^{2+} applications result in membrane depolarisations similar to those evoked by ACh suggests, but does not prove, that the ACh effects are caused by a rise in cytosol Ca^{2+} concentration. Unfortunately the small size of pancreatic acinar cells (10–15 μm in diameter) has prevented the use of photoproteins (such as aequorin) to monitor changes in intracellular Ca^{2+} concentration following cell activation[8,11,12]. It does seem, however, that uncoupling is always caused by a rise in ionised Ca^{2+} concentration[11]. It is therefore of interest that prolonged extracellular ACh application can evoke reversible acinar cell uncoupling (Fig 3). It can also be seen in Fig. 3 that at the stage of ACh-evoked uncoupling, the depolarisation in one cell (the cell into which current pulses are injected) becomes more marked than in the neighbouring cell. When the cells subsequently recouple the effects of short doses of ACh become equal. Such ACh-evoked acinar cell uncouplings were observed repeatedly in four different glands. This phenomenon, which had been postulated on the basis of indirect evidence[13], is probably the most direct demonstration of an ACh-evoked increase in pancreatic acinar cytosol Ca^{2+} concentration available at present.

The new experimental findings that ACh can cause acinar cell uncoupling and that intracellular Ca^{2+} applications can mimic the effect of ACh provide new evidence for the hypothesis that ACh acts primarily on membrane Ca^{2+} translocation[14].

We thank Mrs M. Gordon for technical assistance and the MRC for grant support.

Nuclear localisation of an oocyte component required for the stability of injected DNA

MOST cells contain deoxyribonucleases but do not degrade their nuclear DNA. This paradox is sometimes explained by assuming that the nucleases do not have access to DNA, from which they may be separated by the nuclear membrane. Another possibility is that cells contain a component which stabilises DNA even in the presence of nucleases. We show here that such a component is present in the frog oocyte, a type of cell in which deoxyribonucleases have been repeatedly demonstrated[1,2]. Although we have not characterised this component, we show that it is localised in the nucleus; it seems to be absent from cytoplasm but may leak into it when the nuclear membrane is ruptured. The DNA whose stability we have investigated is a small circular molecule introduced into the oocyte by microinjection, but the conclusions probably apply also to the endogenous nuclear DNA of the oocyte, and perhaps to the nuclear DNA of eukaryotic cells in general.

We performed three types of experiment in which *Xenopus laevis* oocytes were injected with purified ^{3}H-labelled SV40 DNA and then analysed singly by methods which show whether the injected DNA lay within the nucleus or in cytoplasm. First, using autoradiography, we defined the location of ^{3}H-SV40 DNA immediately after injections aimed at the oocyte nucleus (germinal vesicle, GV). Second, individual nuclei and cytoplasms, manually separated, were analysed for their content of ^{3}H-SV40 DNA several hours after injections aimed at either the GV or vegetal pole cytoplasm. Third, the molecular configuration of this recovered DNA was correlated with its location in each oocyte.

Autoradiographs were prepared from sections of 20 oocytes fixed within 5 min of injections aimed at the GV. A common result was that much of the injected DNA was located in an area to one side of the GV (Fig. 1*a*, *b*). In a few cases the labelled DNA was situated exclusively in the cytoplasm. Most significant for this discussion, however, was the fact that in about half of the analysed oocytes, some of the labelled DNA had been deposited clearly inside the GV and had already started to mix with its contents (Fig. 1*c*, *d*).

In the second type of experiment, oocytes whose nuclei contained ^{3}H-SV40 DNA were identified by a method allowing subsequent analysis of the molecular configuration of the injected DNA. Injections of ^{3}H-SV40 DNA were directed either at the GV or into vegetal pole cytoplasm. The GVs were manually removed 24 or 48 h later and ^{3}H-DNA from each GV and cytoplasm was extracted and counted as indicated in the legend to Fig. 2. The results, shown in Fig. 2, demonstrate three points. First, from each oocyte the total radioactivity recovered in acid insoluble form was variable, but the mean for all injected oocytes was almost the same as the total injected radioactivity. Similar recoveries were obtained from oocytes after injection both into the nuclear region (Fig. 2*a*) and into vegetal pole cytoplasm (not shown). Second, ^{3}H-DNA injected into the cytoplasm did not penetrate the GV, even after 48 h (Fig. 2*c*). Third, oocytes injected so as to aim for the GV fell into two classes (Fig. 2*b*). In about half, more than 95% of the recovered DNA was present exclusively in the cytoplasm, a distribution similar to that in oocytes intentionally injected into the cytoplasm. Clearly in these oocytes the injection had either missed the GV or completely leaked out of it, and we refer to them as 'GV-miss' oocytes. In the remainder, referred to as 'GV-hit' oocytes, substantial quantities of ^{3}H-SV40 DNA were present in the GV, in most cases exceeding 80% of the total recovered DNA.

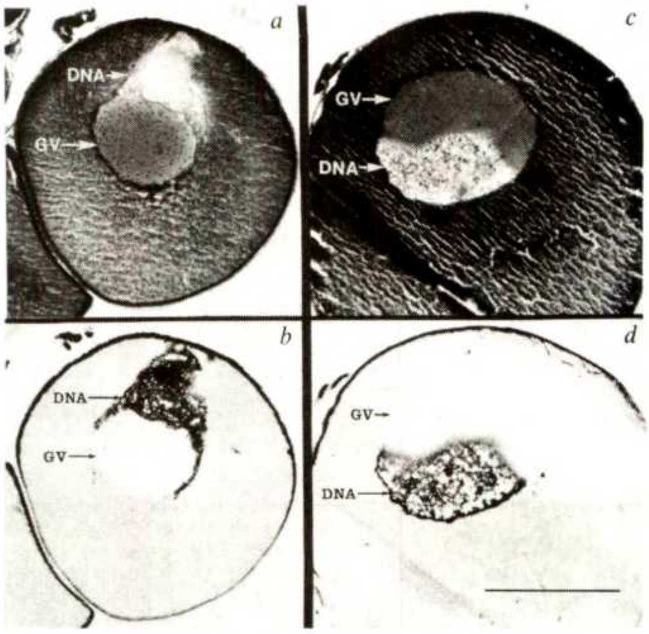

Fig. 1 Intracellular distribution of ^{3}H-SV40 DNA immediately after injection into oocytes. ^{3}H-SV40 DNA (50 nl containing 5 ng) was injected into oocytes[12], aiming for the GV. They were fixed 2–5 min later, for sectioning and staining (*a*, *c*) and subsequent autoradiography (*b*, *d*). In the oocyte shown in *a* and *b*, the injected DNA is located outside the GV. In the oocyte shown in *c* and *d*, the injected DNA is clearly located within the GV, and is already beginning to mix with its contents. Scale bar, 400 μm.

Finally we investigated the configuration of injected DNA recovered from isolated GVs and cytoplasms by methods described in the legend to Fig. 3. Each GV-injected oocyte was classified as 'GV-hit' or 'GV-miss' by counting aliquots of the extracts of nucleus and cytoplasm as described above, and the configuration of the DNA in each oocyte was then correlated with its intracellular distribution. At the time of injection most of the ^{3}H-SV40 DNA was covalently closed and supercoiled (form I), with a small proportion in nicked circular form (form II) (Fig. 3*a*).

DNA deposited directly in the cytoplasm of oocytes was always degraded. It appeared in gels as faint but discrete bands corresponding to the full length linear (form III) and nicked circular (form II) configuration, together with smears representing partially digested linear molecules (Fig. 3*e*); form I DNA was never observed. The absence of any residual covalently closed DNA was confirmed by alkali sucrose gradient analysis of pooled aliquots from these cytoplasms. In most 'GV-miss' oocytes, the DNA recovered from cytoplasm showed a gel distribution closely similar to that of oocytes intentionally injected into the cytoplasm: it was extensively degraded (Fig. 3*d*).

'GV-hit' oocytes showed a strikingly different pattern. First, all the intranuclear ^{3}H-SV40 DNA appeared in gels as a single, sharp form I band; no linear DNA was ever observed (Fig. 3*b*). Second, detectable quantities of ^{3}H-SV40 DNA were sometimes found in the cytoplasms of these oocytes and it is of special interest that in such cytoplasms almost all the ^{3}H-DNA was also in a supercoiled (form I) configuration (Fig. 3*c*). Nicked and linear forms of ^{3}H-DNA were absent or present only in traces. Alkali sucrose gradient analysis of pooled aliquots of 'GV-hit' cytoplasms confirmed the presence of conserved covalently closed ^{3}H-SV40 DNA.

These results show that DNA deposited inside the GV was conserved in supercoiled form, whereas DNA injected directly into cytoplasm was degraded. We interpret the unexpected conservation of DNA in the cytoplasm of 'GV-hit' oocytes as due to leakage of nuclear contents into the cytoplasm. There is direct evidence that such leakage occurred: visibly ruptured GVs were recovered from six GV-injected oocytes, all of which showed form I DNA in their cytoplasm. It seems probable that GV rupture was caused by the large volume of DNA solution injected (50 nl, that is, approximately 1.4 times the volume of the full grown oocyte GV).

Two conclusions may be drawn from these experiments. First, conservation of injected DNA is due, not to its separation from cytoplasmic nucleases by some impermeable membrane, but to a component which renders it stable even in the presence of nuclease. This is demonstrated by the conservation of DNA within the cytoplasm of oocytes in which the GV had been ruptured by injection (cytoplasm analysis of 'GV-hit' oocytes): this conclusion concords with the observed presence of endonucleases within eukaryotic nuclei[3]. Second, the oocyte component responsible for DNA stability is normally localised in the GV.

At this stage, we can make only general observations about the nature of this GV component. It could be a nuclease inhibitor, or a type of molecule which combines with DNA so as to render it resistant to nucleases. We have found that, when conserved, the injected DNA is transcribed[4,5] and is assembled into a nucleoprotein complex whose buoyant density and regularly repeated substructure are those expected of chromatin (A.H.W., J.B.G. and R. A. Laskey, in preparation). However, assembly into chromatin might be a consequence, rather than cause, of DNA stability. In addition to histones[6,7] several other proteins are strongly localised in the GV of oocytes[8,9], and might stabilise DNA.

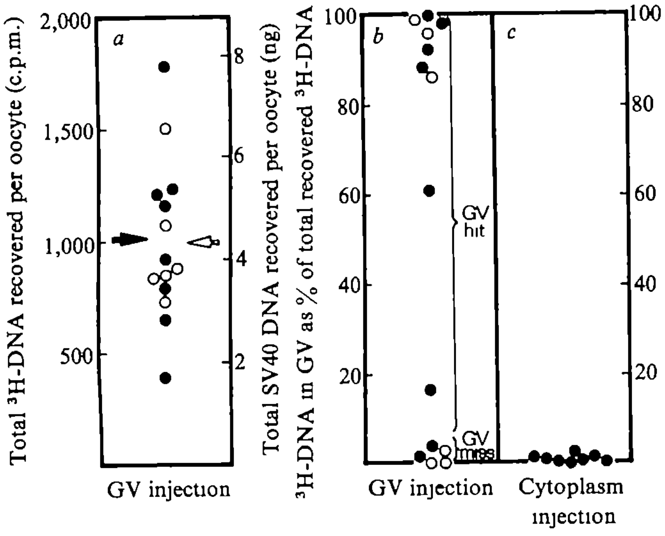

Fig. 2 Location of ^{3}H-SV40 DNA recovered from single oocytes 24 h (○) or 48 h (●) after injection. (*a*) shows, for each oocyte, the total recovered ^{3}H-DNA counts (and hence the total mass of recovered SV40 DNA), taking GV and cytoplasm together. The left hand arrow indicates the mass and radioactivity of DNA in each injection, estimated by delivering the usual oocyte injection volume through the microinjection pipette directly on to a glass chip which was then counted in scintillant. The right-hand arrow shows the mean recovered mass of DNA from these oocytes. (*b*) Refers to oocytes injected aiming for the GV, and (*c*) to oocytes injected in vegetal pole cytoplasm; in both *b* and *c* the counts in each GV are expressed as a percentage of the total counts recovered from the oocyte. Oocytes were injected with approximately 50 nl medium containing 5 ng purified ^{3}H-SV40 DNA, specific activity 380,000 d.p.m. μg^{-1}. After incubation at 19 °C in MBS-H medium[12] for 24 or 48 h, follicle cells were manually peeled off and the GVs were manually removed and washed free of yolk. Each GV and cytoplasm was frozen within 30 s of isolation. ^{3}H-DNA was extracted by making a homogenate of each GV or cytoplasm in 100 μl buffer containing 50 mM Tris, *p*H 7.5, 5 mM EDTA, 0.5% sodium dodecyl sulphate, 0.75 mg ml^{-1} proteinase K and 0.8 mg ml^{-1} yeast tRNA (as carrier). The homogenate was incubated at 37 °C for 2 h and extracted twice in chloroform : isoamylalcohol (24 : 1). The aqueous phase was precipitated in 10% trichloroacetic acid at 0 °C on to Millipore filters which were dried and counted with an efficiency of about 60% in scintillant.

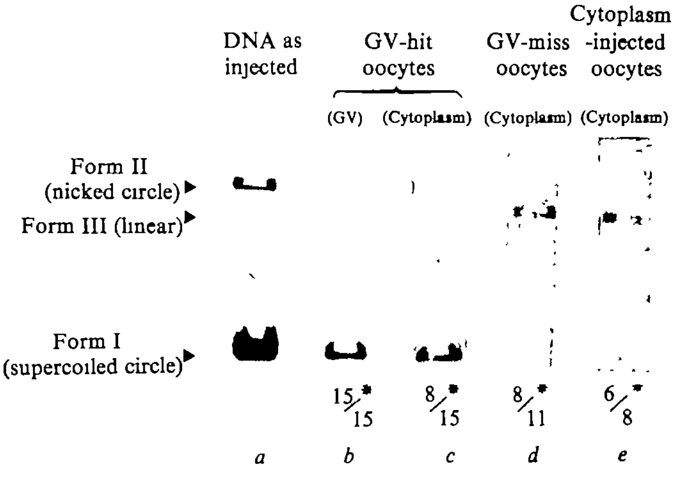

Fig. 3 Conformation of DNA injected into oocytes and recovered from isolated GVs and cytoplasms. GV-injected oocytes, classed as 'GV-hit' or 'GV-miss' as described in Fig. 2, are compared with oocytes injected in vegetal pole cytoplasm. The gel tracks show typical examples of the conformation adopted by ^{3}H-SV40 DNA in the GV of 'GV-hit' oocytes and in the cytoplasm of oocytes of all classes. GVs of 'GV-miss' and cytoplasm-injected oocytes contained neglible amounts of ^{3}H DNA and were not analysed on gels. Seven of fifteen cytoplasms from 'GV-hit' oocytes and two of eight cytoplasms from cytoplasm-injected oocytes differed from the pattern shown in that they contained little ^{3}H DNA and showed no discrete gel bands. Three of eleven cytoplasms of 'GV-miss' oocytes also differed from the pattern shown in that they contained form I DNA. At the time of isolation the GV of one of these oocytes was found to be merely a ruptured membranous sac and we presume that, in the other two cases also, GV material had leaked into cytoplasm. Individual GVs or cytoplasms were homogenised and extracted in chloroform: isoamylalcohol as described in the legend to Fig. 2. An aliquot was removed for scintillation counting to permit GV-injected oocytes to be classified as 'GV-hit' or 'GV-miss', and the remainder was loaded on 1% Agarose slab gels for electrophoresis[13] at 40 mA for 14 h. Thereafter the gel was impregnated with PPO, dried and fluorographed[14]. *Proportion of samples with the gel pattern shown

The behaviour of this GV component at nuclear division is of interest. It is probably released into the cytoplasm when the oocyte nuclear membrane breaks down at the time of maturation into eggs; uncleaved eggs, unlike oocytes, conserve DNA injected into their cytoplasm[10]. This type of component may, we suggest, be of general occurrence in eukaryotic cells, protecting chromosomal DNA from nuclease attack throughout the cell cycle and especially during mitosis.

Conceivably, cytoplasmic nucleases could be of value to cells, ensuring the breakdown of any exogenous DNA taken into the cell. Uptake of exogenous DNA occurs rather frequently as a result of cell death. in the course of the normal cell renewal in many tissues, the products of dead cells—including their DNA—are ingested by their viable neighbours[11]. Phagocytes also may require protection from ingested bacterial DNA. Viral DNA however may be resistant to degradation by virtue of its own core proteins.

Rigid control of synthesis of collagen Types I and III by cells in culture

THE constituents of the extracellular matrix have a fundamental role in the structure and function of all tissues. A major insight into the composition of this matrix came with the discovery[1-3] that interstitial collagen was not homogeneous, but rather composed of two species, termed Type I and Type III. Type I collagen (composed of two $\alpha 1(\mathrm{I})$ chains and one $\alpha 2$ chain) usually forms densely packed fibrils (the cross-banded collagen commonly seen in electron micrographs). In comparison, Type III collagen (composed of three $\alpha 1(\mathrm{III})$ chains) exists, in part, as reticulin, in which fine, randomly dispersed collagen fibrils are intimately associated with other connective tissue components[3,4]. Appreciation of the possible functional significance of the heterogeneity of the interstitial collagens has come from the analysis of the ratio of Type I to Type III collagen in different tissues in health and disease. Most pliable tissues (skin, intestine, blood vessels, lung) have a I : III ratio of 2–3 to 1, while rigid tissues (bone, tendon) contain only Type I collagen[5,6]. Studies of inflammation and wound healing have demonstrated that early granulation tissue (a material with little tensile strength) has a very low I : III ratio[4,7], while mature scar (a stiff tissue) has a high I : III ratio[8]. In addition, disorders associated with a loss of tissue compliance (arterosclerosis[9], pulmonary fibrosis[10]) are associated with a shift in the normal I: III ratio toward relatively more Type I collagen. Taken together, these findings suggest that the structure and function of tissues are intimately associated with the relative amounts of the interstitial collagens, with Type I tightly packed and tough and Type III loosely associated and pliable. If the relative amounts of collagens I and III are as important as this data suggests, the maintenance of normal interstitial tissues must be critically dependent on cells in the local environment rigidily maintaining their differentiated state with respect to the synthesis and degradation of these collagen types. We describe here a study designed to evaluate this hypothesis, using a model system to assess the 'tightness' of cellular control of the synthesis of collagens I and III by a population of similar cells (fibroblasts in culture) over approximately 20 replicative cycles.

To accurately assess the relative rates of synthesis of Types I and III by cells in culture, we adapted cyanogen bromide (CNBr) mapping techniques to quantitate all of the collagen in the culture, regardless of its type, form or location. To increase the accuracy of the quantitation of both collagen types, we used NB-6, a diploid fibroblast derived from the newborn rabbit lung, since it synthesises

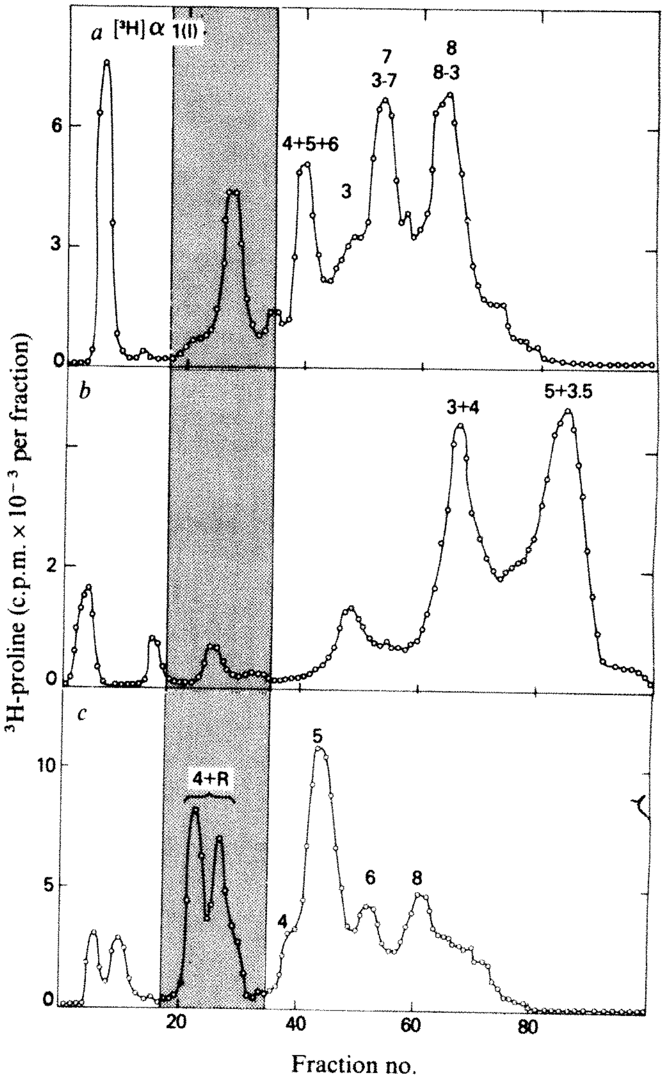

Fig. 1 Quantitation of the ratio of Type I to Type III collagen synthesised by rabbit lung fibroblasts (NB-6) in culture, step 1: carboxymethyl-cellulose (CMC) chromatography of CNBr peptides. NB-6 cells were grown to confluency in 100 mm² plates, rinsed with phosphate-buffered saline (PBS), and labelled for 24 h at 37 °C in Dulbecco's modified Eagle's medium (DMEM) 10 ml per plate, containing 0.3 mM ascorbic aicd, 0.5 mM β-aminoproprionitrile and either 50 μCi ^{14}C-proline (260 mCi mmol^{-1}) per plate or 1.5 mCi ^{3}H-proline (32 Ci mmol^{-1}) per plate. Isolation, morphological characterisation and subcultivation of the NB-6 culture was as previously described[11]. Medium was collected, dialysed against 10 mM Tris-HCl, *p*H 7.4, 2 M urea, and ^{3}H-proline labelled Type I and Type III collagens were prepared using diethylaminoethylcellulose chromatography[11,16]. The ^{3}H-proline labelled Type I collagen was further purified into ^{3}H-α1(I) and ^{3}H-α2 chains by CMC chromatography[17]. Using these methods, the labelled Type III collagen, Type I collagen and α1(I) and α2 chains are greater than 98% pure[11]. To approximate the conditions in which the collagens in an entire tissue culture plate would be quantitated, labelled collagens were added to pooled cells and medium from five unlabelled culture plates, dialysed against 0.1 M acetic acid, lyophilised and CNBr peptides were produced using an excess (100 mg) of CNBr. The CNBr peptides of the purified collagens or their component chains were separated by CMC chromatography (0.9 × 12 cm column; 250 ml × 250 ml, 10 mM to 160 mm NaCl gradient in 20 mM Na-citrate, *p*H 3.8, flow rate 40 ml h^{-1}; 5 ml fractions) and aliquots (0.2 ml) of each fraction were counted in Aquasol. *a*, CNBr peptides of ^{3}H–α1(I) chains synthesised by NB-6 cells in culture; the characteristic peptides are labelled. *b*, CNBr peptides of ^{3}H-α2 chains from the same cultures; α2CNBr (3.5) is probably peptide 3–5; it has a molecular weight[17,18] of approximately 60,000. *c*, CNBr peptides of ^{3}H-Type III collagen. The shaded area ('region A') was used to quantitate the ratio of Type I to Type III collagen synthesised by NB-6.

significant quantities of both collagens I and III (ref. 11).

NB-6 cultures were labelled with ^{3}H-proline in the presence of ascorbic acid and β-aminopropionitrile at subcultivations 5 and 10 at different stages in the cell growth curve. The cultures were labelled for 18 h (in the conditions used, NB-6 cells synthesise collagen in a linear fashion for >24 h) and the resulting ^{3}H-proline labelled proteins solubilised with CNBr. To quantitate the ratio of ^{3}H-Type I to ^{3}H-Type III collagen synthesised by the cultured cells, peptides characteristic of ^{3}H-Type I and ^{3}H-Type III collagens were then isolated by carboxymethyl-cellulose chromatography followed by isoelectric focusing gels (Figs 1 and 2). Region A (shaded area Fig. 1) was chosen for the I: III quantitation for two reasons: (1) it is the least complex region of the Type I and Type III CNBr peptide map, containing only one peptide from Type I [α1(I)CB3] and two peptides from Type III [α1(III)CB4+α1(III)CB(R)] (Fig. 2*a*); and (2) the I and III peptides in region A are clearly separated from each other by isoelectric focusing (Fig. 2*b*); this procedure is quantitative and easily reproducible. The final ratio of ^{3}H-Type I to ^{3}H-Type III synthesised by the cells in culture was determined from a standard curve prepared from known mixtures of ^{3}H-Type I and ^{3}H-Type III previously purified from NB-6 cultures (Fig. 2*c*).

This method obviates a number of technical problems inherent in the quantitation of collagen types synthesised by cells in culture: (1) the use of a standard curve circumvents possible differential losses of I and III during analysis and takes into account the differences in proline+hydroxyproline residues in the I and III peptides used for quantitation; (2) CNBr cleavage of the entire plate ensures that all of the newly synthesised I and III will be quantitated, independent of whether the collagens are in solution in the culture medium, precipitated on the cell layer, or intracellular and also independent of the extent of processing from procollagen to collagen; (3) to ensure that ^{3}H-Type I and ^{3}H-Type III are hydroxylated to the same extent and not contaminated by non-collagen proteins, the isoelectric focusing gels are evaluated by quantitating both ^{3}H-proline and ^{3}H-hydroxyproline in the I and III peptides; and (4) since cross-linked peptides may map differently, β-aminopropionitrile is added to the cultures in concentrations which inhibit cross linking of the newly synthesised collagens[11].

The NB-6 cells synthesise collagen Types I and III in a ratio of 1.94±0.09 (mean ± s.e.m.) to 1 (that is, 66% I, 34% III) over at least 20 replicative cycles (Fig. 3). Thus in conditions in which the extracellular milieu is defined and constant, the fibroblast exhibits remarkably tight control over the relative synthesis of these two collagen types. This holds true even through periods of rapid cell

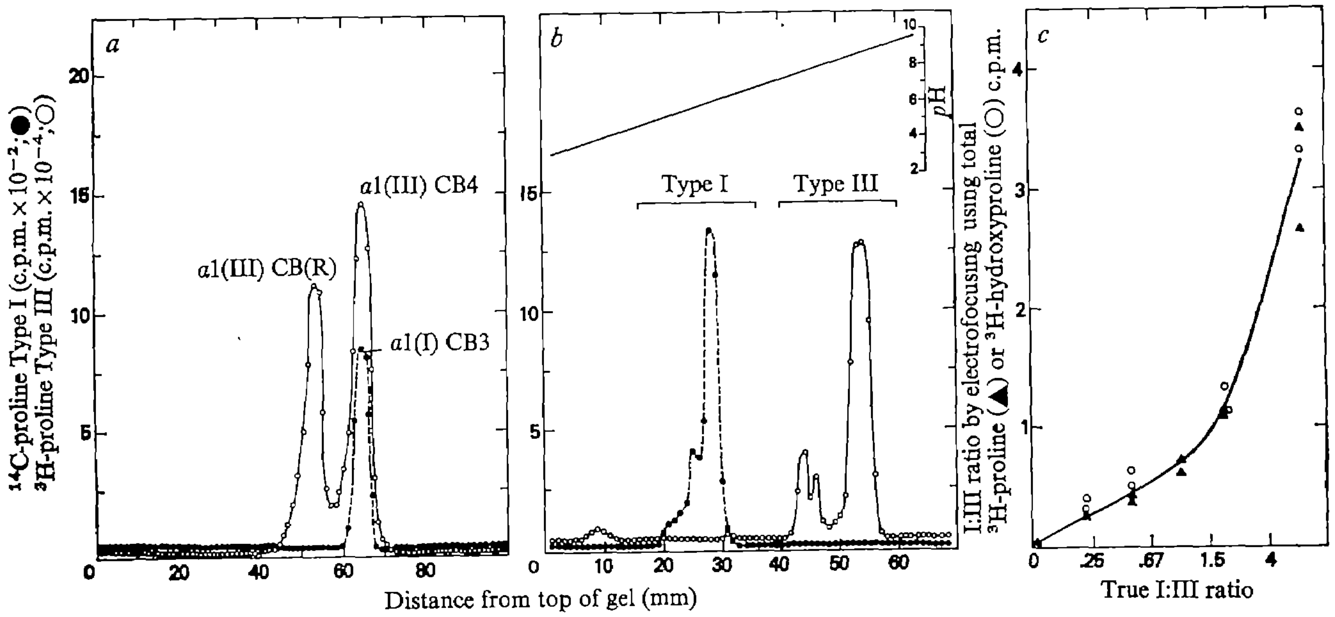

Fig. 2 Quantitation of the ratio of Type I to Type III collagen synthesised by NB-6 cells in culture, step 2: analysis of ^{3}H-labelled CNBr peptides from region A of the CMC chromatogram. A mixture of ^{14}C-Type I and ^{3}H-Type III CNBr peptides were chromatographed on CMC. The A region peptides were precipitated with ethanol (−20°, 18 h, using 500 μg of rabbit skin Type I collagen CNBr peptides as carrier), isolated by centrifugation (72,000*g*, 2 h, 4 °C). *a*, ^{14}C-Type I (●) and ^{3}H-Type III (○) peptides from region A isolated on sodium dodecyl sulphate (SDS)–acrylamide gels. The peptides were dissolved in 1% SDS, 1% β-mercaptoethanol in 0.1 M phosphate buffer, *p*H 7.4 and electrophoresed as previously described[11]. Region A contains one Type I peptide α1(I)CB(3) of approximately 12,000–13,000 molecular weight and two Type III peptides [α1(III)CB4 and α1(III)CB(R)]; α1(III)CB4 electrophoreses with α1(I)CB3 and α1(III)CB(R) electrophoreses with an apparently larger molecularweight. Compared with the α1(I) and α1(III) peptides, there are no significant α2 peptides found in region A. *b*, ^{14}C-Type I (●) and ^{3}H-Type III (○) peptides from region A separated by isoelectric focusing gels. Five-tenths ml of a concentrated acrylamide solution [made up of 3 ml of 30% acrylamide–1% *bis*-acrylamide; 0.3 ml *p*H 3–10 Ampholytes (LKB); 0.7 ml ammonium persulphate (15 mg ml^{-1})]; was added to 1 ml of the A region CNBr peptides at 4 °C, the solution vortexed and used to form a 67×5-mm cylindrical gel. The gels were focused at 1 mA per gel (0.2 M phosphoric acid anode solution, 0.2 M NaOH cathode solution) until 200 V was reached, then 200 V for 5 h total[20]. The *p*H of the focused gels was measured using a micro *p*H electrode (Gel Pro-pHiler, Bio Rad) and confirmed by determining the focusing point of standard proteins[21]. After focusing, the gels were fractionated at 1 mm intervals (Gilson Gel fractionator) and fractions were counted in Aquasol. Alternatively, gels were sectioned at appropriate intervals, hydrolysed in 6 M HCl and the labelled hydroxyproline quantitated[11]. The ^{14}C-Type I peptide [α1(I)CB3] focused at between *p*H 4.5 and 6.5; and ^{3}H-Type III peptides [α1(III)CB4+α1(III)CB(R)] focused between *p*H 7.1 and 8.3. *c*, Various mixtures of ^{3}H-Type I collagen and ^{3}H-Type III collagen synthesised by NB-6 cultures were treated with CNBr along with a fixed amount of ^{14}C-Type III collagen (used to locate region A on CMC) and unlabelled cells and medium from five culture plates. Each mixture was chromatographed on CMC, region A pooled (as determined from the elution pattern of ^{14}C-Type III; see Fig. 1*c*) ethanol precipitated and electrofocused. The Type I region (*p*H 4.5–6.5) and Type III region (*p*H 7.1–8.3) was fractionated and the ^{3}H-proline and ^{3}H-hydroxyproline d.p.m. quantitated. Abcissa: the known ratio of ^{3}H-Type I and ^{3}H-Type III mixed together before CNBr cleavage. Ordinate: the I:III ratio quantitated with isoelectric focusing of CMC region A: ▲, total ^{3}H c.p.m. in the Type I region/total ^{3}H c.p.m. in the Type III region; ○, ^{3}H-hydroxyproline in the Type I region/^{3}H-hydroxyproline in the Type III region. Similar results are obtained using either total ^{3}H c.p.m. or ^{3}H-hydroxyproline. In an actual experiment quantitating the ratio I:III synthesised by NB-6 in culture, the c.p.m. of ^{3}H-hydroxyproline in the Type I region is compared to the c.p.m. of ^{3}H-hydroxyproline in the Type III region and the true I:III ratio read off the abcissa of the standard curve.

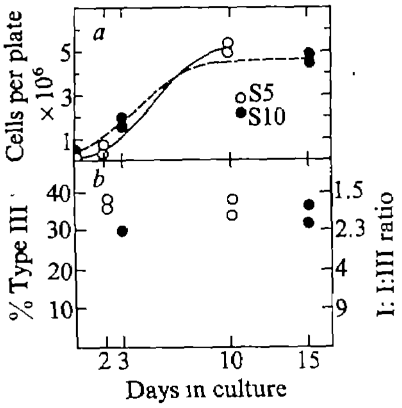

Fig. 3 Quantitation of the ratio of Type I to Type III collagen synthesised by NB-6 cells at two different subcultivations (S5 and S10) and at different times within each subcultivation (early log through late confluency). NB-6 cells in the 4th and 9th subcultivation were detached, counted and plated at a density of 2×10^5 cells per 100-mm² plate in 25 ml DMEM containing 10% foetal calf serum, 100 U ml^{-1} penicillin, 100 μg ml^{-1} streptomycin and 5 μg ml^{-1} fungizone. The medium was replaced every 4th day. For quantitation of the ratio of Type I to Type III collagen synthesised, the NB-6 cells were incubated for 18 h at 37 °C in 4 ml DMEM containing 0.3 mM ascorbic acid, 0.5 mM β-aminopropionitrile and 500 μCi ^{3}H-proline (32 Ci mmol^{-1}). After incubation, the cells were detached by scraping the plates, the cells and medium from five plates were combined, dialysed against 0.1 M acetic acid and lyophilised. Thereafter, the methods described in the legends to Figs 1 and 2 were used. An average of 90% of the ^{3}H-hydroxyproline in the plates was solubilised with CNBr. As a check on the number of cells replicating in the plates at each time, separate plates were incubated under identical conditions with 10 μCi per plate of ^{3}H-methylthymidine (65 Ci mmol^{-1}) for 1 h at 37 °C. After incubation, the cells were washed with PBS, detached, counted and the incorporated ^{3}H-thymidine quantitated. For subcultivation 5, cells at day 10 incorporated 0.1% ^{3}H-thymidine per cell of that incorporated by cells at day 2; for subcultivation 10, cells at day 15 incorporated 0.4% ^{3}H-thymidine per cell as did cells at day 3. *a*, Cell number at early log (days 2–3), late log-early confluency (day 10) and late confluency (day 15) are shown for cells in subcultivation 5(○) and 10 (●). *b*, The ratio of Type I-to-Type III collagen synthesised by NB-6 cells at the same subcultivations and days in each subcultivation as in (*a*). Within the limits of the method, the ratio of I:III was invariant at the times studied with an average of % Type III of 34.1±1.0 (I:III 1.94±0.09).

division. For example, on day 2 of passage 5 the incorporation of ^{3}H-thymidine per cell was 1,000-fold greater than at day 10 of passage 5; even so, the I : III ratio of newly synthesised collagens was identical at both days (Fig. 3). Since 20 population doublings should be ample time for different clonal subpopulations to become apparent[12], these results also suggest, at least for NB-6, all cells in the culture are synthesising collagens I and III at approximately the same ratio. If different clones are characterised by different I : III ratios, the relative number of these clones remains constant in conditions of a defined extracellular milieu.

These results do not imply that fibroblasts never alter the relative amounts of collagen types that they synthesise. In special circumstances when cells become senescent[13,14], or when the extracellular milieu changes, such as in inflammation[15], these cells could change the relative proportions of collagens I and III that they produce, either by altering the differentiated characteristics of each cell or by selecting specific clones emphasising one collagen type. The data presented, however, indicate that in conditions of a constant extracellular environment, the relative ratio of the two known interstitial collagens synthesised by a population of fibroblasts is invariant. Thus, the cells most concerned with the maintenance of interstitial structures are programmed to preserve the status quo by continuing to synthesise the major interstitial components in a carefully controlled fashion.

Long term culture of tumour-specific cytotoxic T cells

MANY investigators have been successful in the maintenance of long term tissue culture of human bone marrow-derived (B) cells. These cell lines have been established from both normal subjects[1] and from patients with lymphoproliferative disorders[2]. In most cases, long term B-cell lines have been shown to harbour the Epstein–Barr virus genome which some investigators feel is required for establishment and maintenance of long-term cultures[3]. There are fewer reports describing continuous culture of human thymus derived (T) cell lines, and when successful, the lines have only been established from patients with acute lymphocytic leukaemia[4]. Although these cell lines have been shown to bear surface markers of normal human T lymphocytes, there have been no reports which suggest that they possess the ability to respond to immunologic stimuli or to differentiate into antigen-specific lymphocytes. Cytotoxic murine T cells have been kept in continuous culture only through repetitive mixed-lymphocyte stimulation[5]. In contrast to long term human lymphocyte lines, these cells proliferated only when stimulated with allogeneic lymphocytes and eventually died after a few weeks in culture. Morgan, Ruscetti and Gallo recently reported a method by which medium conditioned by phytohaemagglutinin-stimulated normal human lymphocytes allowed for the selective long-term growth of normal T cells[6]. In contrast to the previously mentioned cell lines, the proliferation of these reported T-cell cultures was totally dependent on the presence of an exogenously-produced growth factor supplied by the conditioned medium. In this report we describe an adaptation of this method which allows the long term culture of antigen-selected cytotoxic T cells which continue to demonstrate high levels of syngeneic tumour-specific cytotoxicity after more than 4 months in culture.

Cytotoxic T cells were generated in secondary allogeneic mixed tumour–lymphocyte cultures (MTLC). Spleen cells were harvested from normal C57Bl/6 mice and from C57Bl/6 mice immunised with allogeneic (*H-2*^{d}) F4-5 Friend virus (FLV)-induced leukaemia cells (from Dr W. Ostertag, Max Planck Institute, Gottingen, Germany). Both spleen cell populations were co-cultured with mitomycin-treated (100 μg ml^{-1} for 60 min)[7] F4-5 cells in Click's medium (Altick Associates) with 2% heat inactivated foetal calf serum (FCS) for 5 d (responder: stimulator ratio of 40 : 1). Viable cells collected from primary allogeneic MTLC were restimulated with mitomycin-treated F4-5 cells and placed back in culture for a further 2 d. Cultures of cytotoxic cells generated in secondary allogeneic MTLC of normal C57B1/6 spleen cells were designated cytotoxic lymphoid line 1 [(CTLL(1)] and cells collected from repetitive allogeneic MTLC of spleen cells from C57B1/6 mice immunised with F4-5 were designated CTLL(2). The population of cytotoxic lymphocytes collected from secondary allogeneic MTLC was a heterogeneous one in that one lymphoid subpopulation was reactive against allogeneic targets while a second subpopulation contained lymphocytes capable of effecting syngeneic tumour-specific cytotoxicity[13].

Viable cells collected from secondary allogeneic MTLC were placed in continuous culture in 50% Click's medium and 50% growth factor. Growth factor was prepared from 48-h tissue culture medium (RPMI 1640 (GIBCO) with 10% FCS) from cultures of concanavalin A (con A, 2.5 μg ml^{-1}, Miles–Yeda) stimulated normal DBA/2 spleen cells. Growth factor was filtered through a 0.2-μm filter (Nalge–Sybron) to remove subcellular particles before use in long-term culture medium.

Both CTLL(1) and CTLL(2) have remained in continuous proliferative culture for 22 weeks. Representative growth curves for both lines are shown in Fig. 1. Cells seeded at a concentration of 5×10^3 per ml reach a saturation density of approximately 3×10^5 cells per ml after 6 or 7 d in culture thereby demonstrating a doubling time of 24 h. Proliferative growth is totally dependent on the presence of growth factor. CTLL(1) and CTLL(2) cannot be maintained in continuous culture in either Click's medium supplemented with FCS or in RPMI 1640 medium supplemented with FCS and con A.

Cells from cultures of CTLL(1) and CTLL(2) were used periodically as effector cells in lymphocyte-mediated cytolysis (LMC) assays[8], against the allogeneic tumour target cell, F4-5 (Fig. 2) and the syngeneic FLV-induced FBL-3 (Hn), (Fig. 3). Both F4-5 and FBL-3 (Hn) were confirmed as non-virus-producing murine leukaemia cells by reverse transcriptase[9] and X-C assays[10]. When LMC data is expressed in terms of lytic units per 10^6 effector cells (LU $\times 10^{-6}$), the allogeneic cytotoxicity mediated by CTLL(1) increased from 76.9 LU $\times 10^{-6}$ after 3 weeks in culture to 555 LU $\times 10^{-6}$ after 17 weeks in culture. Similarly, allogeneic lysis effected by CTLL(2) rose from 40 LU $\times 10^{-6}$ after 3 weeks of culture to 500 LU $\times 10^{-6}$ 14 weeks later. Results of LMC assays (Fig. 3) indicate that the syngeneic tumour cell lysis mediated by CTLL(1) and CTLL(2) was tumour specific. Although FBL-3 (Hn) murine leukaemia cells were effectively lysed, syngeneic normal cells (C57B1/6 lymph node and con A-stimulated (2.5 μg ml^{-1}) spleen cells remained unaffected). Syngeneic tumour-specific cytotoxicity demonstrated by CTLL(1) effector cells increased from 10 LU $\times 10^{-6}$ after 3 weeks in culture to 333 LU $\times 10^{-6}$ after 17 weeks in culture. CTLL(2)-mediated cytotoxicity of FBL-3 (Hn) cells rose from 16.7 LU $\times 10^{-6}$ following 3 weeks in culture to 142.9 LU $\times 10^{-6}$ after 17 weeks of continuous *in vitro* passage.

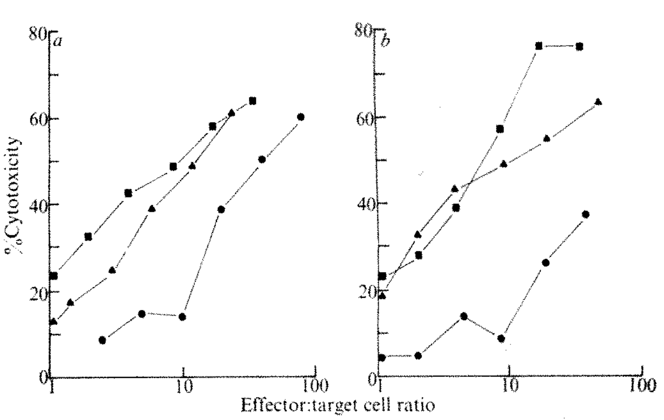

Fig. 2 *a*, Allogeneic cytotoxicity demonstrated by CTLL(1) against the FLV-induced non-producer murine leukaemia cell, F4-5, after 3 weeks (●), after 10 weeks (▲), and after 17 weeks (■), in continuous culture. *b*, Cytotoxicity demonstrated by CTLL(2) against F4-5 after 3 weeks (●), 10 (▲) and 17 weeks (■) in culture. Per cent cytotoxicity was determined in lymphocyte-mediated cytolysis assays which measured Cr^{51} release of radiolabelled target cells. Target cells were labelled with 250 μCi of Na$_2$Cr^{51}O$_4$ (specific activity 100–400 mCi per mg Cr, Amersham–Searle). Target cell concentrations were adjusted in RPMI 1640 with 10% FCS to 0.1 c.p.m. per cell. Target cells (100 μl) were mixed with log$_2$ dilutions of effector cells collected from CTLL(1) and CTLL(2) long term cultures, in V-bottom microplates (1S MVC-96-TC, Linbro Scientific). The Cr-release reaction was stopped after a 4-h incubation at 37 °C by a 10-min 300*g* centrifugation at 4 °C. c.p.m. of Cr-release were determined by counting 100 μl of each well supernatant on a liquid scintillation counter, per cent specific lysis was determined using the following equation

$$\%\text{Specific lysis} = \frac{\text{experimental c.p.m.} - \text{medium control c.p.m.}}{\text{maximum release c.p.m.} - \text{medium control c.p.m.}} \times 100$$

Medium control c.p.m. were obtained from 100-μl supernatant aliquots sampled from microplate wells containing 100 μl of target cells and 100 μl of RPMI 1640 with 10% FCS. Maximum release c.p.m. were generated from microplate wells containing 100 μl of target cells and 100 μl of Zap Isoton Solution (three drops added to 5 ml double distilled H$_2$O), Coulter Electronics, Lytic units were defined as the number of effector cells necessary to cause 30% specific lysis. Growth factor was not present in LMC assays.

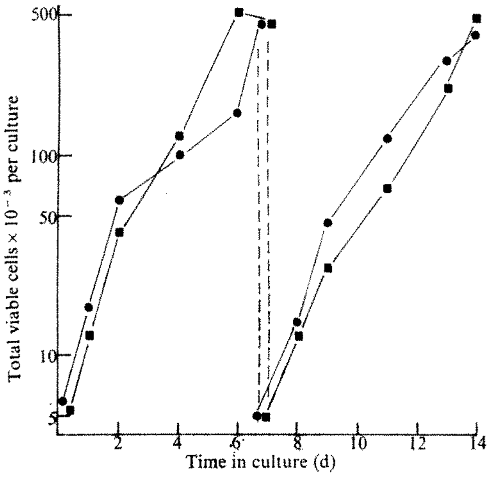

Fig. 1 Representative growth curves of CTLL(1) (●) and CTLL(2) (■). Dotted lines indicate passage of long term cell lines and reseeding of additional culture flasks at the day 0 cell concentration of 5×10^3 cells per ml. Both cell lines exhibited this pattern of proliferative growth provided they were grown in the presence of medium containing 50% growth factor. Click's medium with 50% growth factor was also supplemented with 2% heat-inactivated FCS, 300 μg ml^{-1} fresh L-glutamine, 50 units ml^{-1} penicillin, 50 μg ml^{-1} streptomycin, 16 μmol ml^{-1} NaHCO$_3$ and 25 μmol ml^{-1} HEPES buffer. Cells were cultured in a humified atmosphere of 5% CO$_2$ in air at 37 °C.

Figure 4 shows Wright–Giemsa-stained preparations of CTLL(1) and CTLL(2) after 22 weeks of continuous proliferation *in vitro*. Both cell lines are blastoid and highly vacuolar in appearance, and were lysed by anti-theta serum (AKR anti-C3H thymus from Litton Bionetic) when tested using absorbed rabbit complement[11]. Histochemical stains of both CTLL(1) and CTLL(2) for peroxidase, periodic acid Schiff, napthal chloroacetate and α-napthylacetate esterases, were negative. These tests confirm that the syngeneic tumour-specific cytotoxicity demonstrated by CTLL(1) and CTLL(2) was mediated by cytotoxic T cells maintained *in vitro* with the aid of a growth factor produced by con A-stimulated spleen cells.

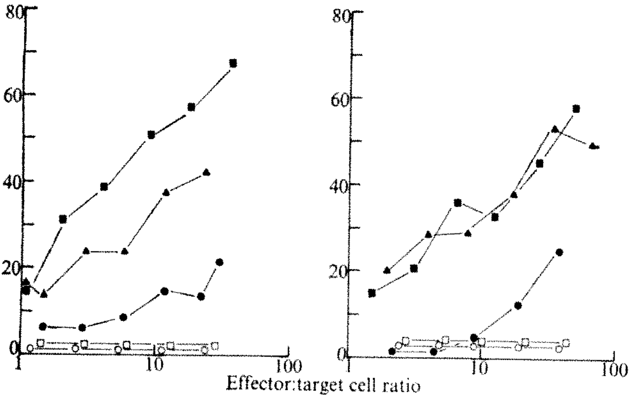

Fig. 3 *a*, Cytotoxicity of syngeneic FBL-3 (Hn) Friend leukaemia cells effected by CTLL(1) cells after 3 (●), 10 (▲) and 17 weeks (■) in culture. Cytotoxicity demonstrated by CTLL(1) against syngeneic normal lymph node (○) and con A-stimulated spleen cells (□). *b*, Cytotoxicity of FBL-3 (Hn) by CTLL(2) cells after 3 (●), 10 (▲), and 17 weeks (■) in culture. CTLL(2)-mediated cytolysis of syngeneic normal lymph node (○) and con A-stimulated spleen cells (□). FBL-3 (Hn) was adapted to continuous *in vitro* culture from ascites-passaged FBL-3 cells, obtained from Dr Ronald Herberman, NCI. LMC assay conditions, and radiolabelling of all target cells identical to those described in Fig. 2.

The continuous proliferation of differentiated T lymphocytes *in vitro* raises questions as to the regulatory factors operating *in vivo* which prevent continuous clonal expansion after antigenic stimulation. The demonstration that continuous proliferation of cytotoxic T cells *in vitro* is possible, suggests that some humoral or cellular factor may be operating *in vivo* to prevent differentiated proliferation. Furthermore, the long term culture system described here might serve as a starting point for the identification and characterisation of these growth promoting and inhibiting, regulatory factors.

Finally, although cytotoxic lymphocytes generated *in vitro* have beeen shown to be effective mediators of tumour cell lysis *in vivo*[12], the inability to generate these cells in large numbers has prevented their widespread use. The ability to propagate large populations of syngeneic tumor antigen-specific cytotoxic lymphocytes through the use of a growth factor, makes possible the testing of these lymphocytes in adoptive immunotherapy. The syngeneic cytotoxic specificities of the long-term T-cell lines tested in this study were directed against non-producer leukaemia cells. Because murine non-producer leukaemia cells represent the model system most analagous to human leukaemia, this study provides evidence that the *in vitro* generation of large numbers of leukaemia-specific human cytotoxic T cells might be possible.

Fig. 4. Wright–Giemsa-stained cytocentrifuge preparations of *a*, CTLL(1) and *b*, CTLL(2) cells after 22 weeks of continuous culture *in vitro*. (×6,000).

Effect of glucose and insulin on collagen secretion by human skin fibroblasts *in vitro*

Increased glucose concentration in the medium in which normal fibroblasts are grown in culture caused an increase in one type of procollagen synthesised, an increase in the incorporation of labelled carbon from glucose into collagen, and an increase in the rate of collagen secretion. The addition of insulin to the culture media did not affect collagen secretion.

Skin fibroblasts growing *in vitro* synthesise collagen when the medium is supplemented with ascorbic acid[1]. Most of this collagenous protein remains soluble in the medium as procollagen types I and III (refs 2–5). The procollagens are secreted by the fibroblasts into the medium where they are eventually cleaved, polymerised and deposited as extracellular insoluble collagen fibrils. Human fibroblasts *in vitro* do not efficiently convert procollagen into collagen, so there is an accumulation of intact procollagen in the medium[6].

Skin biopsy material was obtained from human subjects undergoing surgery for non-metabolic disorders. Fibroblasts were isolated after trypsinisation, and grown as monolayers in minimum essential medium (MEM, Flow Labs) plus 10% foetal calf serum. Ascorbic acid (50 μg ml^{-1}) was added to the culture medium to ensure maximal collagen synthesis[7]. Cells were continuously passaged and monitored periodically for their ability to incorporate tritiated thymidine into DNA (ref. 8). All the experiments reported here were performed on cells at confluency. For 24 h before the experiment, the cells were placed in a serum-free medium (MEM) plus 1% non-essential amino acids. After 24 h, fresh MEM + 1% non-essential amino acids were added and glucose and/or insulin (0.1 U ml^{-1}) was added to the experimental dishes. The medium was removed 24 h later and analysed for collagen-like material according to the technique of Paz and Gallop[9]. Briefly, collagen was isolated by TCA precipitation, hot TCA solubilisation and collagenase (purified by chromatography)[10] treatment and determined by microbiuret analysis using rat-tail collagen as standard. In some experiments, hydroxyproline was determined by the method of Bergman and Loxley[12].

To demonstrate that the material isolated in our assay system contained collagen or procollagen, samples were collected after collagenase digestion, desalted by cation exchange column, and hydrolysed in 6 M HCl for 24 h at 100 °C. Amino acids were analysed on a Beckman 121 M amino acid analyser. In selected experiments, protein labelled with ^{3}H-proline was characterised by DEAE-52 cellulose chromatography[13]. Cells remaining in the dish after removal of the medium were washed, solubilised with alkali, and protein[14] and DNA[15] determinations carried out.

Cells growing in a high glucose medium secreted more collagen than those in glucose at a physiological concentration (Table 1). The addition of insulin did not increase the synthesis or secretion of collagen at glucose concentrations of 1 mg ml^{-1} or 3 mg ml^{-1} in the medium. Insulin did, however, stimulate the accumulation of non-collagen protein in the monolayer cells. We conclude that the increase in cell protein (data not given) is part of an insulin stimulation of growth. In the range of glucose concentrations of 1–5 mg ml^{-1}, increasing amounts of collagen were found in the media of the fibroblasts, but above this range no further increase was noted (Table 2).

DEAE-52 cellulose chromatography of the labelled medium collected after 24 h of high and normal glucose treatment gave a radioactive profile similar to that described by others[2,3,5,16]. Normally we find three peaks; first a very small peak which is native collagen, a second large peak which is procollagen type I and a third peak which is presumably procollagen type III. In glucose-treated cultures there is a substantial (30–50%) increase in the third peak. Salt-extracted ^{3}H-labelled collagen from the cellular material remaining attached to the culture chamber gave identical DEAE-52 profiles with 24 h of 1 mg ml^{-1} or 3 mg ml^{-1} glucose treatment.

Table 1 Effect of glucose and insulin on the amount of collagen secreted by fibroblasts into the medium

Experiment	Control	Glucose (3 mg ml^{-1})	Insulin (0.1 U ml^{-1})	Gluscose + insulin
1	0.066	0.115	0.047	0.100
2	0.131	0.193	0.141	0.197
3	0.152	0.207	0.185	0.227
4	0.102	0.139	0.053	0.147
5	0.086	0.182	0.068	0.167
Mean	0.107	0.167	0.097	0.168
± s.e.m.	0.015	0.017	0.027	0.022

The amount of collagen secreted into the serum-free medium by fibroblasts during a 24-h period expressed as μg collagen per μg monolayer cell protein in each culture dish Collagen was measured in duplicate by microbiuret assay against rat-tail collagen. Total monolayer cell protein per dish was determined by dissolving the monolayer in alkali and using an aliquot of this in standard protein determination against bovine serum albumin. In these experiments the amount of protein in each culture dish remained fairly constant, the amount of collagen increased by 50% after the addition of glucose. Insulin had no effect. The data are the mean of five experiments ± the standard error of the mean.

Amino acid analysis of extracted collagen demonstrated twice as much hydroxyproline in each sample of the high glucose medium than in the normal. Colorimetric analysis for hydroxyproline gave similar results; for example 24 μg collagen in the control medium and 36 μg collagen in the glucose-treated medium.

We wondered whether the increased secretion was a result of increased cell proliferation, however, in our growth conditions neither the incorporation of tritiated thymidine in DNA nor the total DNA content was increased by raising the glucose concentration of the medium. In addition, there was no visible evidence (using phase-contrast microscopy) of increased proliferation of fibroblasts in high glucose media. There was no significant difference in cell protein or cell counts with increased glucose concentration in the medium. Rheinwald and Green[17] also reported no increase in cell density at high glucose levels.

Table 2 Effects of glucose concentration on collagen secretion by fibroblasts

Experiment	Glucose concentration (mg ml^{-1})				
	1	2	3	5	7
1	0.049		0.081	0.131	0.149
2	0.058		0.080		
3	0.072	0.108	0.138		

The effect of glucose concentration on the amount of collagen secreted into the medium by fibroblasts, expressed as μg collagen in the medium per μg monolayer cell protein as described in Table 1. There is a dose-dependent response of human diploid fibroblasts to increased glucose concentration in the medium. At glucose concentration of 5 mg ml^{-} or higher, the stimulation of collagen accumulation in the medium began to level off. The amount of protein associated with the monolayer remained constant.

In one experiment, the incorporation of ^{14}C from glucose into collagen was measured. The amount of label incorporated into collagen was 85% greater in cells grown in medium containing 3 mg ml^{-1} glucose than in cells grown in 1 mg ml^{-1}. The addition of insulin did not increase the incorporation of label into collagen. We are now trying to determine whether the labelled carbon residues are in the polypeptide chain or in the disaccharide portion of collagen.

Rechler and Podskalny[18] have demonstrated insulin receptors in fibroblasts but many investigators cannot demonstrate insulin effects in cultured cells. Shaw and Amos[19] have shown that fibroblasts deprived of glucose become highly responsive to insulin; however, cells growing at ≥1 mg ml^{-1} glucose do not respond to insulin by increased glucose uptake. At these glucose concentrations therefore, glucose transport into the cells is gradient dependent and insulin independent. In our experiments the addition of insulin did not cause an additive effect on collagen secretion.

These data suggest that the ambient glucose concentration of fibroblasts can influence the amount, the type, and possibly the glycosylation of collagen secreted by these cells. The implications of this are of great importance to the diabetic patient. Recently, a highly glycosylated haemoglobin molecule, HbA$_{1C}$, has been found in increased amounts in poorly controlled diabetics[20]. Basement membranes isolated from kidney glomeruli of diabetic patients show a marked increase in the carbohydrate components linked to hydroxylysine of the collagenous protein[21]. The offspring of the diabetic mother are also exposed to hyperglycaemia and these infants are born with a variety of defects in development[22]. The ubiquitous presence of collagen throughout the body, its prime role as an inducer in early embryogenesis[23,24], and its susceptibility to structural changes have encouraged us to pursue further the regulation of synthesis and secretion of this molecule in the developing human organism.

We thank Mary Ann Pesce for technical assistance, and Drs Paul Gallop, Mercedes Paz and Robert Spiro for helpful suggestions. This work was supported by a grant from the Milton Fund of Harvard Medical School and the National Foundation.

Spontaneous and induced cell-mediated reactivity to syngeneic cells

IN general, the immune system does not react with self-antigens to produce disease. Potential self-reactive clones are known to exist, however, and are thought to be controlled by thymic-derived suppressor lymphocytes (suppressor T cells). We have investigated the possibility that self-reactive clones of cells are expressed in B/W mice, and that such clones in other inbred mouse strains might become expressed after immunisation with specific antigens of the group A streptococcus. Our studies show that spleen cells from B/W mice respond spontaneously to syngeneic heart cells and to syngeneic kidney cells. In contrast, spleen cells from another inbred strain of mice, the BALB/c, do not respond spontaneously to syngeneic cells. A response to syngeneic cardiac determinants can, however, be induced in the BALB/c mouse by immunisation with cell membranes of group A streptococci.

Many observations, in both human and animal populations, suggest that at times self-reactivity (autoimmunity) does occur. One animal model of autoimmunity is the New Zealand Black/White hybrid mouse (B/W) (refs 1–3). In B/W mice, an imbalance of immune regulation precedes the onset of clinical autoimmune disease. Although the immunobiological events that result in autoimmune phenomena and the mechanisms by which these phenomena lead to pathological changes remain obscure, it has been proposed that the behaviour of T cells is critical to the development of autoimmunity[4–9]. T-cell suppressor function seems to be lost in the older B/W mouse, since exaggerated antibody responses to various antigens, such as type III pneumococcal polysaccharide and polyinosinic-polycytidylic acid, occur[5–9]. Further evidence for the loss of suppressor T-cell function is suggested by the decrease of concanavalin A-induced suppressor function in ageing mice[10]. Other T-cell functions also seem to be lost, since lymphoid cells from older B/W mice do not mount a graft against host response when transferred into allogeneic recipients.

Repeated exposure to antigens that cross react with self-determinants may induce an immune response that eventually results in autoimmunity. Repeated infections with group A streptococci are thought to be an essential factor in the pathogenesis of acute rheumatic fever[11]. Immunological cross reactions between streptococcal and mammalian antigens have been demonstrated, and these cross reactions seem to be mediated by antibodies specific for antigens of the streptococcal cell surface[12–15]. In addition, there are several reports which suggest that cell-mediated cross reactions between streptococcal and mammalian antigens also may occur[16–18].

In our experiments we used primary cultures of syngeneic heart, liver or kidney prepared from neonatal B/W or BALB/c mice. The hearts, livers and kidneys from sex-matched neonatal mice were removed, minced in Hank's calcium and magnesium-free balanced salt solution, trypsinised, treated with mitomycin-C to block DNA synthesis, and resuspended in Eagle's minimal essential medium supplemented with 10% heat-inactivated foetal calf serum. These cell suspensions served as stimulator cells. Responder cells were obtained from the spleens of mice 2–12 months of age. Several groups of BALB/c mice were first immunised with suspensions of group A streptococcal cell membranes. Spleen cells were prepared as single-cell suspensions in the medium described. Responder spleen cells (1.8×10^5) and stimulator cells (1.8×10^4) from heart, kidney or liver were mixed and incubated for 6 d. On the sixth day, all cultures received 2 μCi of tritiated thymidine, were incubated for an additional 24 h, and the amount of radioactive label incorporated into the acid-insoluble fraction of the cells was determined. Measurements of triplicate samples are reported as a stimulation index (SI)± standard error of the mean (s.e.m.); the SI is the ratio of the mean d.p.m. of responder cells in stimulated culture minus the d p m. of stimulator cells alone to the mean d.p.m. of responder cells alone.

The response of the responder spleen cells after incubation with syngeneic or with allogeneic stimulator cells is shown in Table 1. B/W spleen cells responded to syngeneic heart and syngeneic kidney cells as well as to BALB/c heart cells, but did not respond to syngeneic liver cells. On the other hand, BALB/c spleen cells from unimmunised animals did not respond either to syngeneic heart or kidney cells or to heart cells from the histocompatible B/W mice. Sets of BALB/c mice were inoculated with group A streptococcal cell membranes, and their spleen cells were shown to respond to stimulation by streptococcal cell membranes Spleen cells from these immunised BALB/c mice strongly reacted to both BALB/c heart cells and B/W heart cells, but did not respond to syngeneic kidney cells. The responsiveness of spleen cells from older B/W mice to syngeneic heart and syngeneic kidney cells persists, although they no longer respond to phytohaemagglutinin or concanavalin A (unpublished).

These findings demonstrate the existence of clones of cells in the B/W mouse that are spontaneously capable of responding to syngeneic cardiac and renal determinants. In addition, a similar response to syngeneic cardiac determinants can be induced in the BALB/c mouse by immunisation with cell membranes of group A streptococci. The response in the B/W mouse is present in young mice (1–2

Table 1 Response of spleen cells to syngeneic or allogeneic cell populations

Responder cells	Stimulator cells	SI±s.e.m.
B/W	B/W Heart	38.7±4.7
	B/W Kidney	9.5±0.2
	B/W Liver	1.3±0.4
	BALB/c Heart	92.2±7.1
BALB/c (unimmunised)*	BALB/c Heart	0.6±0.0
	BALB/c Kidney	0.0±2.9%†
	B/W Heart	0.0±1.3%†
BALB/c (immunised)‡	BALB/c Heart	82.0±0.3
	BALB/c Kidney	1 8±0.1
	B/W Heart	42.2±1.2

*The unimmunised BALB/c responder cells cultured with streptococcal cell membranes yielded an SI of 1.2±0.1, whereas the immunised BALB/c responder cells yielded an SI of 25.7±1.9 when cultured with the same cell membrane preparation.

†Responder cultures displayed less incorporation of ^{3}H-thymidine than control cultures of stimulator cells alone. SEM is reported as a percentage of the average of triplicate samples.

‡Immunised with group A type 14 streptococcal cell membranes.

months old) as well as in older mice (10–12 months old). These data are consistent with studies suggesting that the disturbance of immune regulation in the B/W mouse may include an early loss of suppressor T-cell function. A loss of suppressor T-cell function may well set the stage for the onset of autoimmune disease. Although these findings may shed some light on the pathogenesis of autoimmune disease in general, as well as that of rheumatic carditis, the observations that cell-mediated reactivity to syngeneic cardiac cells can occur spontaneously or can be induced by microbial antigens may be of broad immunobiological significance.

Inhibition of platelet aggregation by a placental substance with prostacyclin-like activity

The demonstration that certain arteries and veins have the ability to generate from prostaglandin (PG) endoperoxides an unstable substance called prostacyclin (PGI$_2$) (ref. 1), which will inhibit platelet aggregation[2,3], should lead to a reappraisal of the homeostatic mechanisms preventing thrombosis. It has been suggested that the endothelium of these blood vessels contains an enzyme which is capable of converting PG endoperoxides from circulating platelets into an unstable substance, prostacyclin. This inhibits platelet aggregation and so prevents the initial step of thrombus formation within the vessel[4]. Damage to the endothelium of the vessel wall may prevent production of the enzyme PGI$_2$ synthetase, and the subsequent reduction in the local synthesis of prostacyclin could facilitate platelet aggregation in the area of damage. Maintenance of an adequate circulation within the placenta is critical to foetal well-being. This circulation is one both of low pressure and velocity and the presence of a substance which has a potent inhibitory effect on platelet aggregation would seem desirable for its maintenance. We demonstrate here the ability of normal placental tissue to generate a labile substance which has the ability to inhibit ADP-induced platelet aggregation. The properties exhibited by this substance are suggestive of it being PGI$_2$.

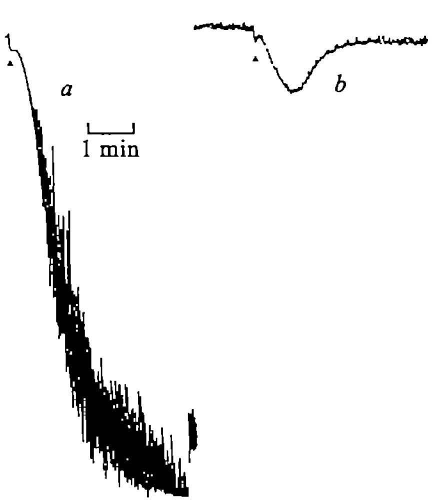

Fig. 1 Aggregation of platelet rich plasma (PRP) pre-incubated with placental tissue. PRP was prepared from citrated plasma by centrifugation at 2,000 r.p.m. for 10 min. Aggregation was induced by addition of ADP to a concentration of 5 µm (▲). *a*, The control response of 0.9 ml PRP to ADP. *b*, The effect of pre-incubation of 0.9 ml PRP with 10 mg washed placental tissue for 20 min at 22 °C before addition of ADP.

Venous blood was collected from the same subject who had not taken prostaglandin synthetase inhibitors for at least 2 weeks. Citrate solution 3.1% (9 : 1, v/v) was used as the anticoagulant and platelet rich plasma (PRP) and platelet poor plasma were prepared by centrifugation. Platelet aggregation was carried out as previously described[5], using ADP in a final concentration of 5 μM.

Pieces of placental tissue (10–40 mg) were taken at random from the maternal surface immediately after delivery. In all cases the pregnancies and deliveries were entirely normal. The placental pieces were washed several times to remove blood and kept in Krebs solution gassed with 95% O$_2$: 5% CO$_2$ until use.

Pre-incubation of PRP with placental tissue inhibited subsequent ADP-induced platelet aggregation (Fig. 1). Incubation of placental tissue in Tris buffer and the subsequent addition of an aliquot of the supernatant to PRP quantitatively inhibited ADP-induced platelet aggregation. Heating of this supernatant at 37 °C for 10 min or boiling for 0.25 min abolished its anti-aggregatory properties (Fig. 2). Platelets aggregated by previous addition of ADP could be disaggregated by the addition of an aliquot of supernatant derived from incubation of placental tissue in Tris buffer (Fig. 3).

Pretreatment of placental tissue with indomethacin did not affect its anti-aggregatory properties when subsequently incubated with PRP, whereas pretreatment with tranylcypromine abolished the anti-aggregatory activity (Fig. 4).

These experiments show that placental tissue can spontaneously generate a substance which inhibits platelet

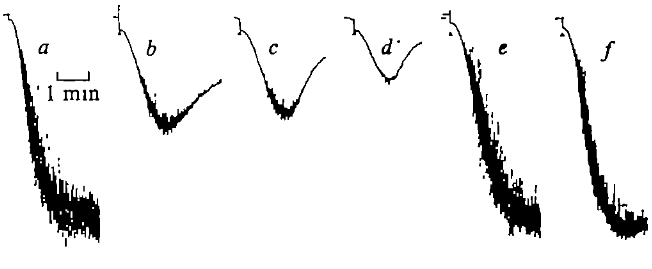

Fig. 2 Effects on platelet aggregation of supernatant from placental tissue incubated in buffer. 40 mg of placental tissue was incubated in 500 µl 0.05 M Tris, *p*H 7.5 for 20 min at 22 °C. The supernatant was added in varying amounts. *a*, 0 µl; *b*, 25 µl; *c*, 50 µl and *d*, 100 µl—each added to 0.9 ml PRP and incubated for 1 min at 37 °C before addition of ADP 5 µM. The same experiments were carried out using 100 µl of supernatant which had been boiled for 0.25 min (*e*) or heated at 37 °C for 10 min (*f*).

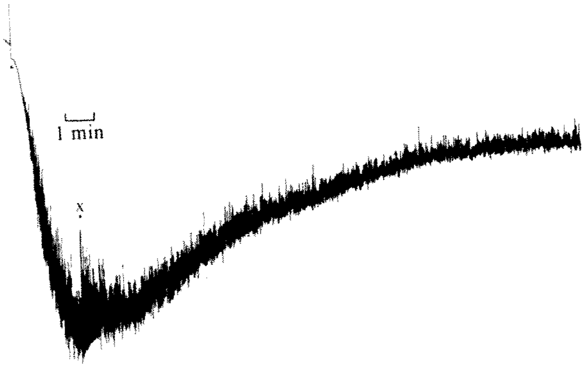

Fig. 3 Reversal of ADP-induced platelet aggregation by supernatant from placental tissue incubated in buffer. 0.9 ml PRP was aggregated by addition of ADP (▲) and reversal of aggregation caused by addition at (X) of 100 μl supernatant from 20 mg placental tissue incubated in 200 μl 0.05 M Tris, pH 7.5 for 20 min at 22 °C.

aggregation. Addition of placental tissue itself (Fig. 1) or supernatant from tissue incubated in buffer at room temperature (Fig. 2) to PRP causes significant inhibition of ADP-induced platelet aggregation. Abolition of the anti-aggregatory activity by heating at 37 °C for 10 min or boiling for 0.25 min (Fig. 2) is in agreement with observations on the instability of prostacyclin[3]. Our findings that supernatant from placental tissue incubated in buffer can disperse preformed platelet aggregates (Fig. 3) is in agreement with the findings of other workers[6,7], confirming that this unstable substance affects platelet aggregation by means other than direct competition with thromboxane A_2 (ref. 8).

Pretreatment of the tissue with indomethacin, an inhibitor of the cyclo-oxygenase enzyme[9] prevents formation in the tissue of PG endoperoxides and primary PGs known to inhibit platelet aggregation. Incubation of this indomethacin-treated tissue wih PRP still inibits platelet aggregation (Fig. 4). This suggests that the enzyme PGI_2 synthetase which may be present in the placenta is unaffected by indomethacin and can act on platelet endoperoxides to produce prostacyclin.

Pretreatment of placental tissue with tranylcypromine, a known inhibitor of PGI_2 synthetase[4] does abolish the inhibition of platelet aggregation seen when placental tissue is incubated with PRP (Fig. 4).

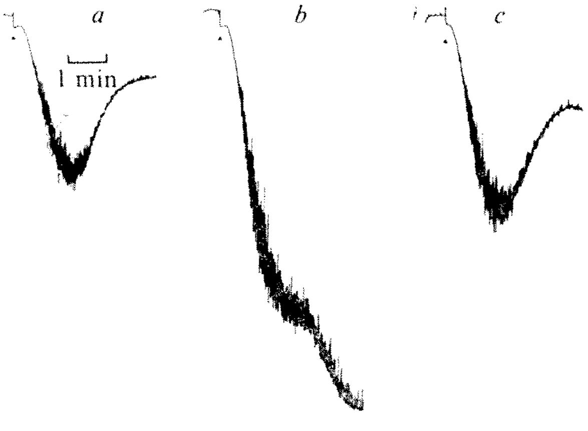

Fig. 4 Treatment of placental tissue with inhibitors of enzymes in the prostaglandin synthetic pathway. 20 mg of placental tissue was incubated for 20 min at 22 °C in a, 200 μl 0.05 M Tris, pH 7.5; b, 200 μl tranylcypromine (50 μg ml^{-1} in 0.05 M Tris, pH 7.5); c, 200 μl indomethacin (1 μg ml^{-1} in 0.05 M Tris, pH 7.5.). The tissue was removed, washed three times in Tris buffer before incubation with 0.9 ml PRP for 15 min at 22 °C and subsequent addition of ADP (▲).

Thus placental tissue when in contact with platelets seems to generate an unstable substance, inhibiting platelet aggregation and exhibiting the previously described properties of prostacyclin. The generation of this substance could be an important factor in the maintenance of placental circulation. Localisation and measurement of the PGI_2 synthetase capacity, which these experiments suggest might be present in the placenta, is the next step in understanding the homeostasis of the placental circulation. The decreased rate of platelet disaggregation in the plasma of patients suffering from placental insufficiency[10] is suggestive of decreased prostacyclin levels or PGI_2 synthetase capacity.

Prostacyclin is the major prostaglandin released from the isolated perfused rabbit and rat heart

PROSTACYCLIN (prostaglandin X, PGI_2), a newly discovered prostaglandin[1-3], is formed by microsomes from several organs, such as pig and rabbit aorta[2] and rat stomach[4], and by fresh human arterial and venous tissue incubated with PGH_2 (ref. 5). As inhibitor of blood platelet aggregation, it is 30 times more potent than PGE_1 (ref. 2) and could thus help in preventing the formation of intra-arterial thrombi. It has been suggested[1] that the endoperoxides released by the platelets can be converted into prostacyclin by vascular tissue. Prostacyclin is chemically unstable in aqueous solution: it hydrolyses to 6-oxo-$PGF_{1\alpha}$ (refs 3, 4; Fig. 1) which does not inhibit platelet aggregation[2]. We report that isolated perfused rabbit and rat hearts produce a labile factor which strongly inhibits blood platelet aggregation; the release of this substance is abolished by indomethacin. Using a physicochemical method, we found 6-oxo-$PGF_{1\alpha}$ in substantial amounts in the perfusates. These findings indicate that prostacyclin is the major prostaglandin released from the heart.

Hearts were perfused with a Krebs–Henseleit buffer solution according to Langendorff or as modified by De Deckere and Ten Hoor[12]. The latter method is based on the observation that in the isolated perfused heart a small part (2–5%) of the perfusion fluid reaches the surface of the heart through the interstitial space and the lymphatics. This smaller flow is separated from the main flow by tying off the veins of the right and left atrium and cannulating the pulmonary artery. Most of the perfusion fluid is ejected by the right ventricle through the cannula (Q_{rv}), a small amount passes the interstitium and drips from the heart (Q_i). As the flow rate of Q_i is small, the concentrations of substances released into Q_i are relatively high.

Prostacyclin-like activity was determined direct in Q_i by measuring the inhibition of ADP-induced rat platelet aggregation (Fig. 2)[6]. The biological activity was standardised against PGE_1. As rat platelets are insensitive to PGD_2 and PGE_2,

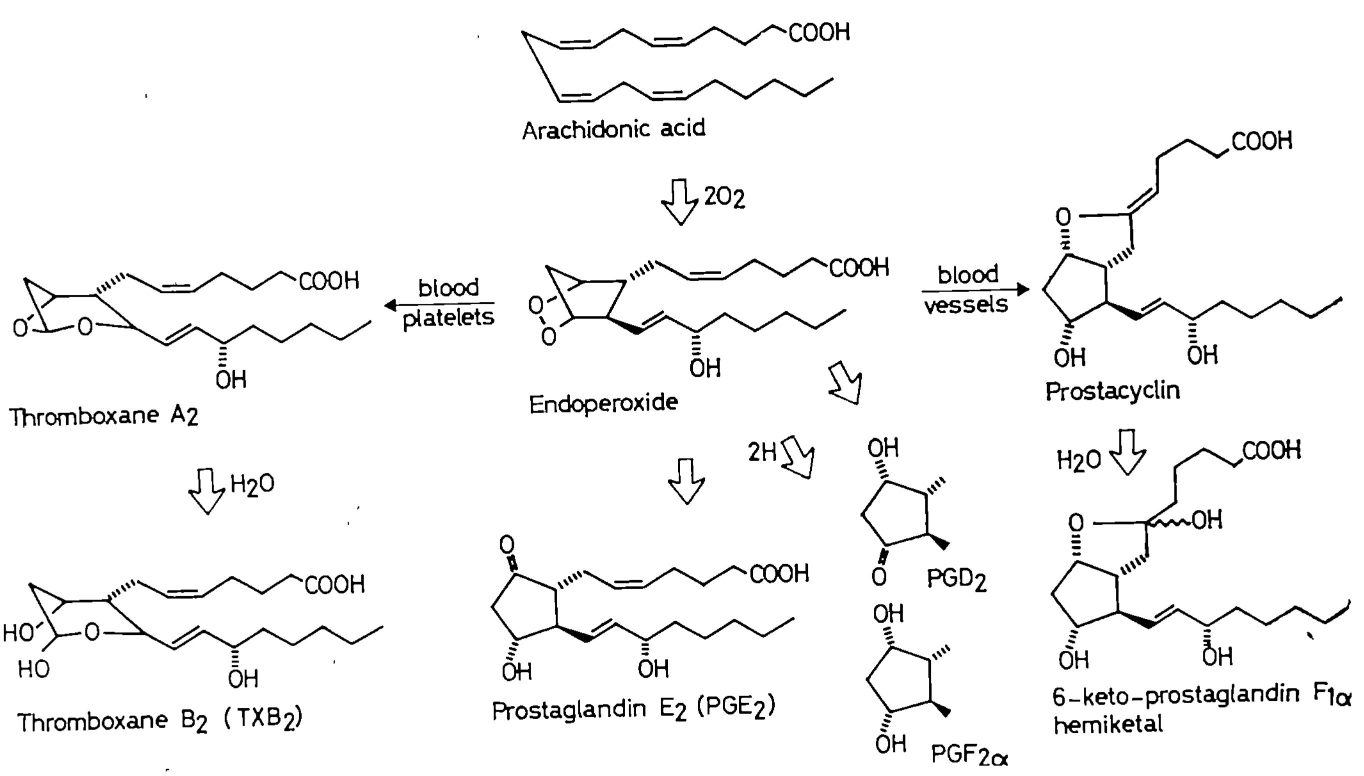

Fig. 1 Routes in the metabolism of prostaglandin-endoperoxide.

interference from 'stable' prostaglandins in Q_1 cannot be expected. PGE_2-like activity was assayed on the isolated gerbil colon[7] in ethyl acetate extracts of acidified perfusates. Antagonists were used as described previously[8]. PGE_2, PGD_2, $PGF_{2\alpha}$, TXB_2 (thromboxane B_2) and 6-oxo-$PGF_{1\alpha}$ (Fig. 1) were extracted, purified by thin-layer chromatography as their methoximated pentafluorobenzyl esters and, after silylation, determined by gas chromatography with electron-capture detection[9] (Table 1). Figure 3 gives examples of the results of the determination of PGE_2, $PGF_{2\alpha}$ and 6-oxo-$PGF_{1\alpha}$.

The isolated perfused rabbit heart released at least twice as much 6-oxo-$PGF_{1\alpha}$ as PGE_2, the amount (8–12 ng per min per g dry weight) being more than that of all other prostaglandins together (Table 2). The results of the bioassay on the gerbil colon and the gas-chromatographic determinations of PGE_2 correlate reasonably well. Since 6-oxo-$PGF_{1\alpha}$ is the stable hydrolysis product from prostacyclin, it is most probably prostacyclin that was released from the isolated rabbit heart. Freshly collected Q_I showed a distinct inhibition of platelet aggregation (Fig. 2 and Table 3), an ability which disappeared after incubating Q_I for 10–15 min at 37 °C. Perfusion of the heart with indomethacin (1 μg ml^{-1}) completely abolished the anti-aggregatory activity of the perfusate; anoxia for 6 min increased this activity only moderately. Because of the much greater dilution, no inhibition of platelet aggregation could be detected with Q_{IV}, although in this perfusate 6-oxo-$PGF_{1\alpha}$ was present according to gas chromatography.

Perfused rat hearts also released 6-oxo-$PGF_{1\alpha}$ (Table 3) as the major prostaglandin, but anoxia did not increase prostaglandin output. In ten rat hearts Q_I was collected for 5 min

Table 1 R_f values of the methoximated (MO) pentafluorobenzyl (PFB) esters after TLC and retention times (R_t) of the trimethylsilylated (TMS) derivatives during GLC

Compound*	%†	R_f (MO·PFB)	R_t‡ (MO·PFB·TMS) (min)	Compound*	%†	R_f (MO·PFB)	R_t‡ (MO·PFB·TMS) (min)
PGD_2	90	0.69	16.0	Thromboxane B_2	43	0.46	19.8
	10	0.57	14.7	(TXB_2)	57	0.38	19.8
PGE_2	74	0.54	17.5	6-oxo-$PGF_{1\alpha}$	58	0.37	22.0
	26	0.46	15.2		42	0.31	22.2
ω-nor-PGE_2	68	0.53	14.2	$PGF_{2\alpha}$	—	0.28	15.2
	32	0.45	12.3	$PGF_{1\alpha}$	—	0.25	17.8

100 ng ω-nor-PGE_2 (ref. 10) and 100 ng $PGF_{1\alpha}$ in 1 ml methanol were added to the perfusates as internal standards. (For the experiment of Table 2, the two standards were added after extraction) The solution was then acidified with HCl (6 mol l^{-1}), drop by drop, until *p*H 4.0. The perfusates were extracted twice with equal volumes of ethyl acetate. The extract was taken to dryness *in vacuo* at 30 °C and the residue rinsed with 2–6 ml methanol into a small test tube. The solvent was removed with nitrogen, and 0.2 ml 2% methoxyamine HCl in pyridine was added. After 16 h at 20 °C, the greater part of the pyridine was removed with nitrogen; 0.5 ml H_2O was added and the prostaglandins were extracted with 2×2 ml ether. To the residue of this extraction, 30 μl pentafluorobenzylbromide was added followed by 60 μl 10% diisopropylethylamine in acetonitrile[9]. After standing for 1 h at 20 °C, the solvents were again removed with a nitrogen stream. The residue was applied as a 2-cm band on a 0.25-mm thick silica gel Fertigplatte (Merck) and developed with chloroform–methanol (90:6, v/v). The appropriate bands were scraped off the plate and eluted with 1–2 ml ether–methanol (2:1, v/v). The eluates were evaporated, the residue was silylated with 25 μl *bis*-(trimethylsilyl)-trifluoroacetamide–pyridine (1:1, v/v) for 1 h at 20 °C and excess reagent removed with nitrogen. Between 0.5 and 5 ng of the PFB esters was injected for gas chromatography, giving sufficiently large peaks with the electron-capture detector.

*Authentic prostaglandins used as references and standards were obtained by biosynthesis from the corresponding unsaturated fatty acids or by incubating PGH_2 with blood platelets (TXB_2) or with sheep aorta microsomes (6-oxo-$PGF_{1\alpha}$).

†The methoximes were present as two isomers (*syn* and *anti*) in the ratio as indicated. $PGF_{2\alpha}$ and $PGF_{1\alpha}$ cannot give a methoxime.

‡2% SE 30, $l = 150$ cm, $d = 0.2$ cm, at 230 °C; carrier gas: argon–10% methane, 25 ml min^{-1}. A Hewlett–Packard 5700 A gas chromatograph with a linear electron capture detector 18713 A was used.

Table 2 Prostaglandin release (ng per min per g dry weight) from the isolated, perfused rabbit heart after anoxia

Group	Gerbil colon	Gas chromatography				
	PGE_2-like activity	PGE_2	PGD_2	$PGF_{2\alpha}$	TXB_2	6-oxo-$PGF_{1\alpha}$
1 (n=8)	4.7±0.6	3.5	0.9	1.8	2.2	9.3
2 (n=8)	3.3±0.5	3.9	1.2	1.8	2.1	9.9

In two separate experiments, eight rabbit hearts (about 0.7 g dry weight) were perfused according to Langendorff (for details, see Table 3). Fifteen minutes after starting the perfusion, the hearts were perfused with an oxygen-free buffer for 3 min. The buffer was then reoxygenated and the perfusion fluid collected for 10 min to give about 400 ml perfusate per heart. This fluid, after acidification, was extracted with ethyl acetate (Table 1). Aliquots of the extracts were tested individually for PGE_2-like activity; PGE_2 served as standard. The other prostaglandins found in the perfusate have relatively little activity on the gerbil colon. The remaining parts of the samples were pooled in the two groups of eight and the five prostaglandins determined in triplicate.

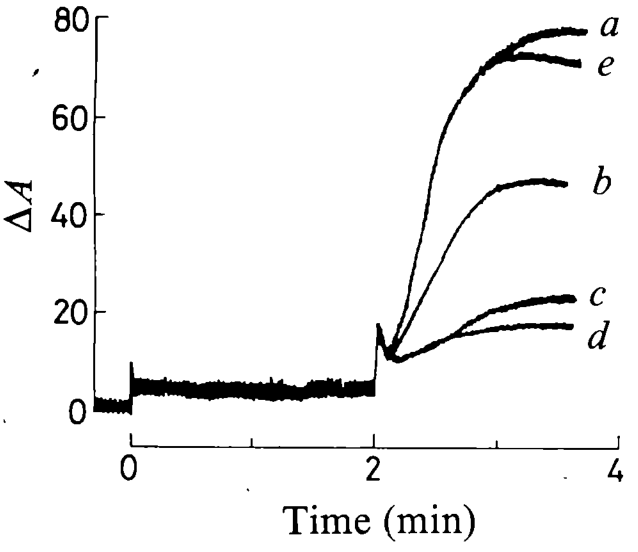

Fig. 2 Inhibition of ADP-induced rat platelet aggregation by freshly collected interstitial effluent Q_i from the isolated perfused heart. Changes in absorbance (ΔA) of rat platelet-rich plasma (PRP; final volume 3 ml) in a modified Vitatron photometer at 37 °C. At $t = 0$, 0.2 ml buffer solution (Krebs–Henseleit) (*a*), 0.2 ml buffer solution with a PGE_1 concentration of 60 (*b*) or 120 ng ml^{-1} (*c*), 0.2 ml of Q_i (*d*) or 0.2 ml of Q_i heated at 37 °C for 15 min (*e*) was incubated with PRP for 2 min ADP (final concentration 94 ng ml^{-1}) was then added to induce aggregation. Tracings have been superimposed. As prostacyclin is assumed to be 30 times more potent than PGE_1 (ref. 2), it can be calculated that in this case Q_i contains 4.5 ng ml^{-1} prostacyclin. Tracing *e* shows that heating of Q_i abolishes its anti-aggregatory activity.

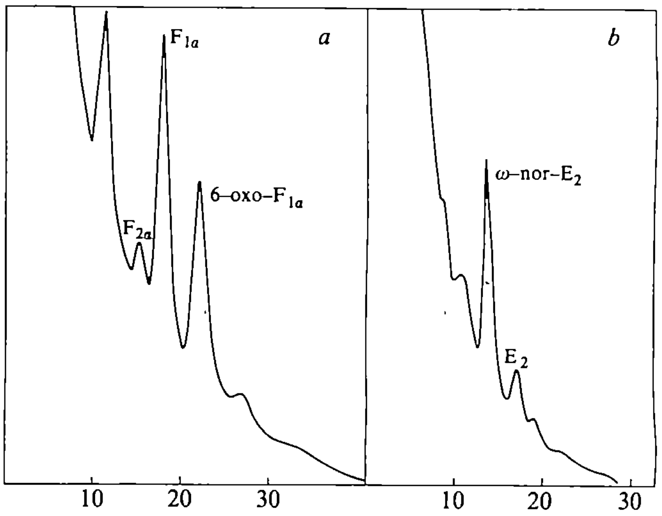

Fig. 3 Gas-chromatographic results of the determination of $PGF_{2\alpha}$ (*a*), 6-oxo-$PGF_{1\alpha}$ (*a*) and PGE_2 (*b*) in rabbit heart perfusates. The methoxime-pentafluorobenzylester-trimethysilylether derivatives were used for the electron-capture detection. $PGF_{1\alpha}$ (100 ng) and ω-nor-PGE_2 (100 ng) had been added as internal standards. Attenuation × 128. For experimental details, see Table 1.

(from 20 to 25 min after starting the perfusion). The prostacyclin-like activity was determined by the platelet aggregation test, the prostacyclin production being 3.3±0.4 ng per min per g dry weight. In four of ten hearts, the prostacyclin release, observed for 1 h at 15-min intervals, was nearly constant. As the release of prostacyclin into Q_i and Q_{rv} is about the same, the total release of prostacyclin from the rat heart can be estimated from the amount released into Q_i.

Our results show that prostacyclin is the major prostaglandin released from perfused rabbit and rat hearts. The negligible amount of thromboxane B_2 found in the perfusion fluid renders it likely that there are hardly any blood platelets present in the isolated perfused heart. This indicates that the heart can synthesise prostacyclin direct from arachidonic acid. We also found that the amount of prostacyclin released from the heart is almost constant during perfusion for more than 1 h, and that it is abolished by infusion of indomethacin (1 μg ml^{-1}). Moncada and co-workers found that in rabbit and pig aortas[1] and in human arteries and veins[5] prostacyclin is almost exclusively synthesised from prostaglandin endoperoxides. They suggest that *in vivo* endoperoxides originating from blood platelets, in active contact with the endothelial layer, are converted into prostacyclin. Our results show that the rabbit and rat heart can synthesise prostacyclin in the absence of blood platelets.

The physiological consequences of these findings cannot yet

Table 3 Prostacyclin and prostaglandin release (ng per min per g dry weight) from the isolated perfused rabbit and rat heart

	Rabbit			Rat				
	Perfusate	Prostacyclin	6-oxo-$PGF_{1\alpha}$	PGE_2	PGD_2	$PGF_{2\alpha}$	TXB_2	6-oxo-$PGF_{1\alpha}$
Before anoxia	Q_{rv}	—	2.7	2.9	<0.5	0.5	0.6	2.2
	Q_i	4.2	4.0	0.5	<1	0.4	0.3	3.1
Following anoxia	Q_{rv}	—	2.2	1.2	n.d.*	0.6	n.d.*	1.8
	Q_i	6.2	8.7	0.7	n.d.*	0.2	n.d.*	1.7

Hearts were perfused with a Krebs–Henseleit buffer solution, gassed with O_2–CO_2 (95:5) and supplemented with glucose (11.1 mmol l^{-1}) and EDTA (0.5 mmol l^{-1}), by the modified Langendorff technique of De Deckere and Ten Hoor[11]. Perfusion pressure was 60 mmHg for rabbit hearts, 80 mmHg for rat hearts; stimulation frequencies were 250 and 360 min^{-1}. Twenty minutes after starting the perfusion Q_{rv} and Q_i were collected for 20 min from two rabbit hearts (about 1 g dry weight per heart; hearts were dried at 80 °C for 24 h; dry weight was about 20% of wet weight) and four rat hearts (about 0.2 g dry weight per heart) to give a total of 1400 ml Q_{rv} and 22 ml Q_i from the rabbit hearts and 1,200 ml Q_{rv} and 30 ml Q_i from the rat hearts. Next, the rabbit hearts were perfused with a buffer, gassed with N_2–CO_2 (95:5) for 6 min, the rat hearts for 5 min. Following this anoxic period, the perfusion fluid was reoxygenated and Q_{rv} (rabbit 850 ml, rat 600 ml) and Q_i (rabbit 40 ml, rat 20 ml) were collected for 10 min. Prostacyclin-like activity was determined direct in fresh Q_i samples collected on ice under N_2–CO_2 (95:5), using the blood platelet aggregation assay[6] and assuming an activity of 30 times that of PGE_1 (ref. 2). Prostaglandins were determined by gas chromatography.

*n.d., Not determined.

be estimated. The continuous production of prostacyclin by the heart and the anti-aggregatory and vasodilatory activity suggest that the main function of prostacyclin production is to protect the coronary circulation against the formation of blood platelet aggregates, thus preventing the occlusion of small branches of the vulnerable coronary tree. If the present results are extrapolated to the human heart, prostacyclin could be a key substance with respect to the origin[11] as well as the prevention of coronary diseases.

C. Gardien and J. F. A. Quadt are thanked for their technical assistance, and G. H. Jouvenaz for helping with the gas-chromatographic determinations.

Transitory expression of Thy-1 antigen in skeletal muscle development

A CELL surface differentiation antigen known as Thy-1 (formerly called theta[1]) is expressed during development of brain and thymocytes in both rat and mouse (see ref. 2 for review). Thy-1 is present in brain and on thymocytes throughout adult life, as well as on a subpopulation of peripheral lymphocytes. Both rat and mouse fibroblasts, and some fibroblastic cell lines, express Thy-1 *in vitro*[3] and mouse Thy-1 has been reported on epidermal cells (see ref. 2 for review) and a mammary tumour[4]. The Thy-1 antigen has been reported lacking in other adult tissues, including muscle[1]. We present here evidence for an antigen with the serological specificity of Thy-1 on rat myogenic cell lines and embryonic rat muscle differentiating *in vitro*. The presence of the antigen was transitory, being expressed on myoblasts and newly developed myotubes, but disappearing as myotubes differentiated.

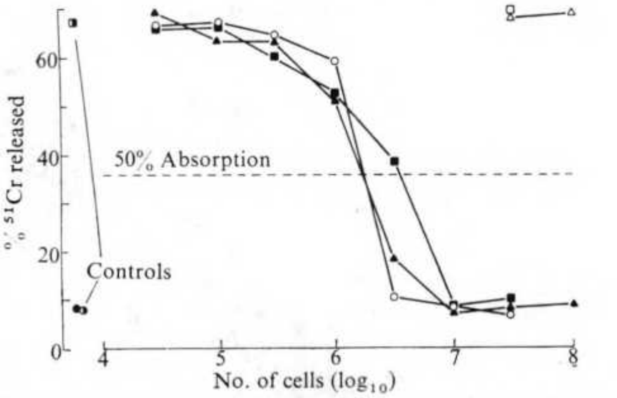

Fig. 1 Exponentially growing cells were harvested in HEPES buffered medium containing 2% FCS (ABM/FCS). L6 and M3A were loosened from the dishes before cell collection by incubation at 37 °C for 5 min in phosphate buffered saline (PBS) lacking Ca^{2+} and Mg^{2+} and containing 2 mM EDTA. Graded numbers of cells were added to ATS (0.2 ml of a 1:80 dilution in HBM/FCS) for 45 min at 4 °C, then removed by centrifugation. Residual antibody was assayed by adding 0.1 ml of absorbed ATS to ^{51}Cr-labelled SIA target cells (2×10^5) in 0.2 ml HBM/FCS containing fresh rat serum complement at a dilution of 1:8. After 45 min at 37 °C, 2 ml HBM/FCS was added, the tubes were centrifuged for 10 min at 475 g, and supernates and pellets were counted separately. %^{51}Cr release was calculated as follows

$$\frac{\text{c.p.m. in supernate}}{\text{c.p.m. in supernate}+\text{c.p.m. in pellet}}\times 100$$

Cell lines used for absorption were: ○, SIA; ▲ C58[NT]D; ■, L6; △, S194; □, M3A. Controls were ^{51}Cr SIA target cells: ●, alone (spontaneous lysis); ○, with rat complement; □, with rat complement + unabsorbed ATS at 1:80.

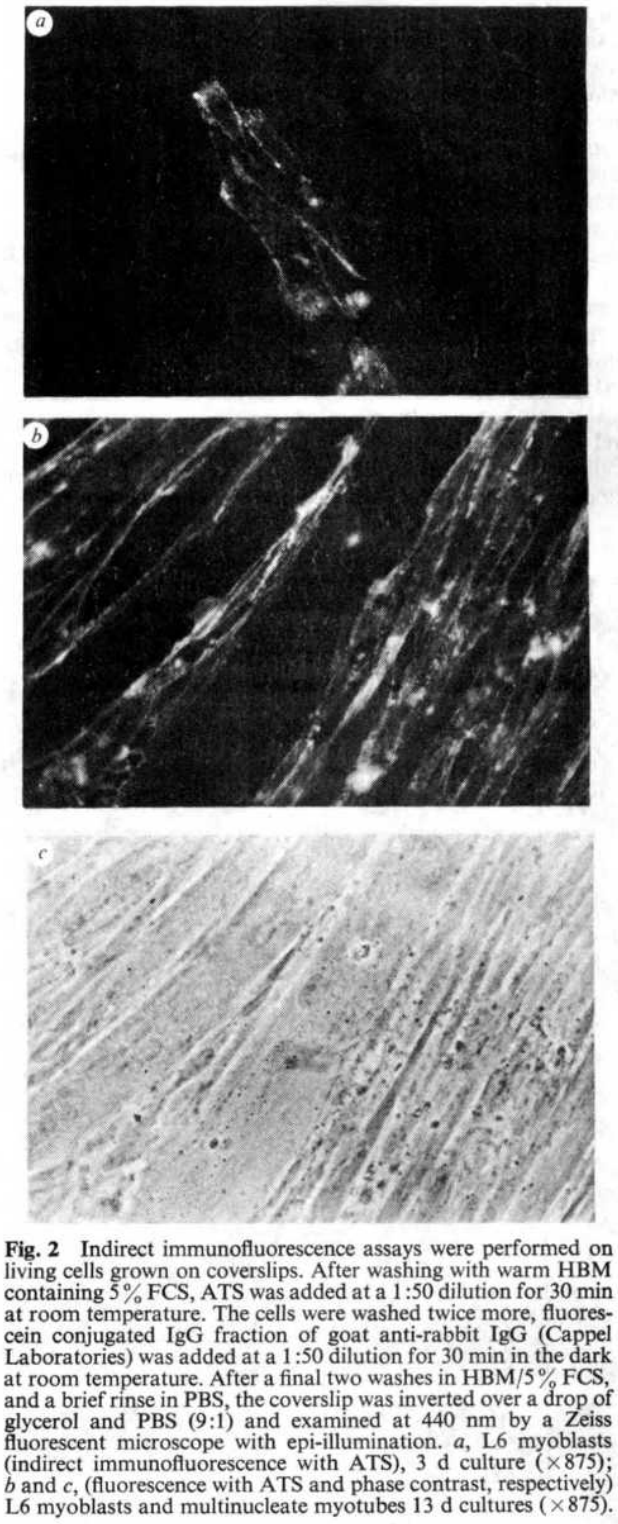

Fig. 2 Indirect immunofluorescence assays were performed on living cells grown on coverslips. After washing with warm HBM containing 5% FCS, ATS was added at a 1:50 dilution for 30 min at room temperature. The cells were washed twice more, fluorescein conjugated IgG fraction of goat anti-rabbit IgG (Cappel Laboratories) was added at a 1:50 dilution for 30 min in the dark at room temperature. After a final two washes in HBM/5% FCS, and a brief rinse in PBS, the coverslip was inverted over a drop of glycerol and PBS (9:1) and examined at 440 nm by a Zeiss fluorescent microscope with epi-illumination. *a*, L6 myoblasts (indirect immunofluorescence with ATS), 3 d culture (×875); *b* and *c*, (fluorescence with ATS and phase contrast, respectively) L6 myoblasts and multinucleate myotubes 13 d cultures (×875).

Rabbit anti-rat-thymocyte serum (ATS) was raised by injecting 10^9 Lewis rat thymocytes, intraperitoneally weekly together with *B. pertussis*, and intradermally every 6–12 weeks with complete Freund's adjuvant. Complement dependent cytotoxicity was titrated on rat thymocytes. Sera of high cytotoxic titres were pooled, heated at 56 °C and absorbed sequentially at 4 °C with rat red blood cells, liver and kidney. A similarly raised and absorbed antiserum was reported to have specificity for purified Thy-1 glycoprotein (see ref. 5). Full details of our pooled antiserum's specificity will be published elsewhere (J.F.L. and V.A.L., in preparation). Its Thy-1 specificity was established by the following criteria: (1) complement dependent cytotoxicity for rat and mouse Thy-1 bearing lymphocytes and lymphomas but not for mouse myelomas; (2) absorption of cytotoxicity against a mouse lymphoma by Thy-1 positive mouse lymphomas, but not by Thy-1 negative variants[6]; (3), absorption by rat brain and thymus, but not by liver, kidney, adult muscle or red blood cells; and (4), precipitation of the 25,000 molecular weight glycoprotein T25 (bearing Thy-1 allospecificity[7]) from ^{125}I-labelled proteins solubilised from rat and mouse thymocyte surfaces.

Thy-1 was assayed by quantitative absorption of cytotoxicity[8] and by indirect immunofluorescence. In assaying for residual antibody after absorption, mouse rather than rat Thy-1 bearing lymphomas were used as cytotoxic targets to ensure detection of a Thy-1 specificity since T25 was the only detectable molecule precipitated from mouse thymocytes by ATS.

Cell lines assayed included: cloned rat myogenic lines, L6 (derived by repeated subculture of foetal limb muscle[9]) and M3A (a non-fusing variant of L6 (ref. 10)), a W/Fu rat thymoma (C58[NT]D (ref. 11)), a BALB/c mouse lymphoma bearing Thy-1 (SIA (ref. 12)) and a BALB/c myeloma (S194 (ref. 12)). All cells grew in suspension in Falcon Petri dishes in Dulbecco's modified Eagles medium (DMEM) with 10% foetal calf serum (FCS), except L6 and M3A which grew attached to Falcon tissue culture dishes and were harvested with 2 mM EDTA for absorption assays.

Figure 1 illustrates the results of absorption assays. Cytotoxicity of ATS for the Thy-1 bearing target SIA was 50% absorbed by 1.5×10^6 rat or mouse thymoma cells. This is approximately twice the absorptive capacity of rat thymocytes. Fifty per cent cytotoxicity was absorbed by 3.0×10^6 L6 myoblasts. Thus the absorptive capacity of each L6 cell approximated that of a thymocyte. Estimation of cell surface area allowed calculation of the approximate antigen density represented by the absorption capacities (see ref. 8). When rounded up after harvesting the

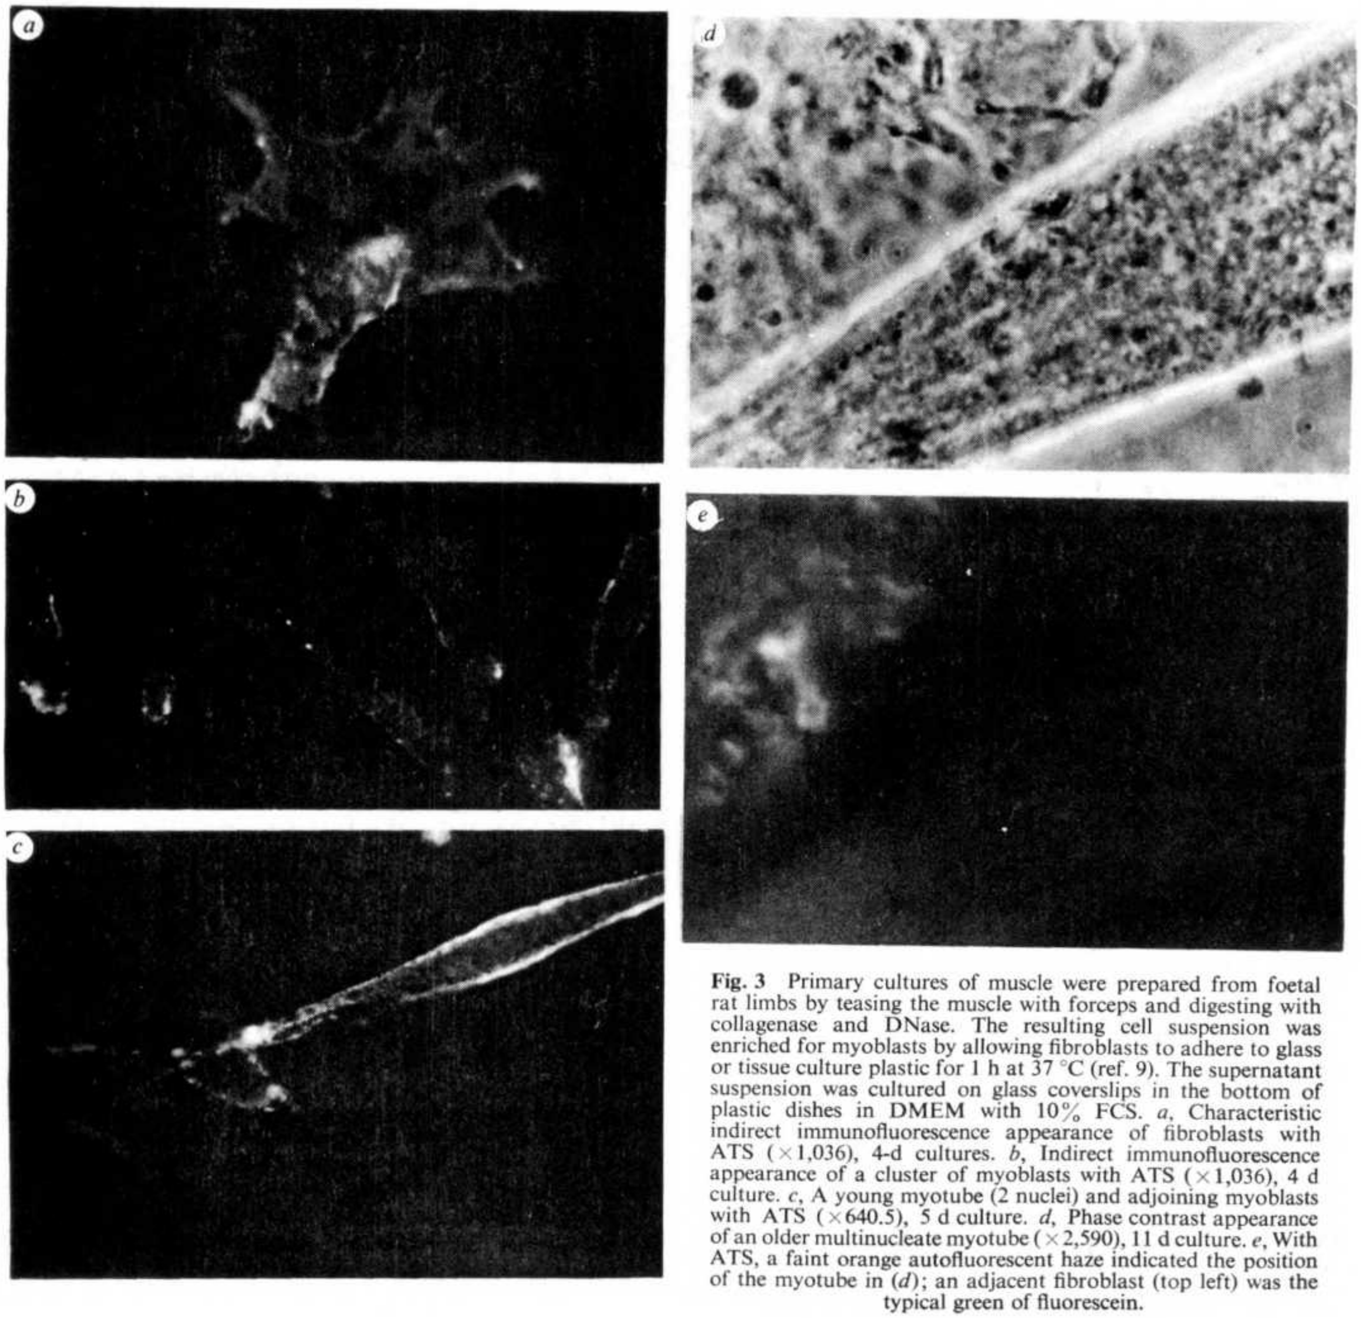

Fig. 3 Primary cultures of muscle were prepared from foetal rat limbs by teasing the muscle with forceps and digesting with collagenase and DNase. The resulting cell suspension was enriched for myoblasts by allowing fibroblasts to adhere to glass or tissue culture plastic for 1 h at 37 °C (ref. 9). The supernatant suspension was cultured on glass coverslips in the bottom of plastic dishes in DMEM with 10% FCS. *a*, Characteristic indirect immunofluorescence appearance of fibroblasts with ATS (×1,036), 4-d cultures. *b*, Indirect immunofluorescence appearance of a cluster of myoblasts with ATS (×1,036), 4 d culture. *c*, A young myotube (2 nuclei) and adjoining myoblasts with ATS (×640.5), 5 d culture. *d*, Phase contrast appearance of an older multinucleate myotube (×2,590), 11 d culture. *e*, With ATS, a faint orange autofluorescent haze indicated the position of the myotube in (*d*); an adjacent fibroblast (top left) was the typical green of fluorescein.

antigen density of the L6 myoblast was approximately one-third that of a thymocyte. M3A, its non-fusing variant, and S194, a myeloma, did not absorb ATS activity, indicating lack of Thy-1 antigen (less than 0.5–1 % of thymocytes).

As L6 cells mature, myoblasts fuse forming multinucleate myotubes which bear nicotinic acetylcholine receptors, are contractile, contain enzymes characteristic of mature muscle and are capable of forming functional cholinergic synapses when co-cultured with appropriate neurons[13]. We noticed that older L6 cultures containing many large myotubes (14 d after plating) absorbed less ATS cytotoxicity than cultures of recently plated myoblasts. The distribution of antigen on L6 was examined by indirect immunofluorescence with ATS (Fig. 2). With fine focus adjustment uniform speckling was observed over the surface of all myoblasts (Fig. 2*a*). L6 cells incubated with either ATS previously absorbed with rat brain or with fluoresceinated anti-rabbit IgG alone, were not fluorescent. In older cultures large, multinucleate L6 myotubes lacked surface fluorescence, in contrast to surrounding myoblasts (Fig. 2*b* and *c*).

Immunofluorescence studies of Thy-1 in cultured foetal muscle are complicated by the presence of fibroblasts, which express Thy-1 (ref. 3). The modified spindle shape of a typical myoblast (Fig. 3*b*) distinguishes it from flattened irregular-shaped fibroblasts (Fig. 3*a*). In early primary cultures all cells fluoresced with ATS, the pattern on primary myoblasts being similar to L6 myoblasts. The density of fluorescent speckles on individual primary myoblasts varied considerably, however. The brightest myoblasts resembled L6 in both pattern and intensity of fluorescence; others had fewer speckles distributed randomly over the cell surface. The surface fluorescence of newly formed myotubes, with just a few nuclei, appeared more dense and brighter than that of adjacent myoblasts (Fig. 3*c*). Fluorescence on myoblasts, young myotubes and fibroblasts was absorbed by rat brain, but not by adult muscle or liver. Mature multinucleate myotubes (Fig. 3*d*) were virtually invisible under blue light (Fig. 3*e*).

Further evidence for the Thy-1 specificity of immunofluorescence on cultured muscle cells includes the following: (1) Rat brain cell lines which were negative for Thy-1 by absorption assay failed to fluoresce with ATS while those positive by absorption were also positive by immunofluorescence (J.F.L. and V.A.L., in preparation). (2) The positive immunofluorescence of mouse primary muscle cultures with ATS, was absorbed by a Thy-1 positive lymphoma, but not by its Thy-1 negative variant[6]. (3) Primary rat myoblasts and fibroblasts were positive by indirect immunofluorescence using an antiserum raised against T25 (ref. 7), a glycoprotein bearing Thy-1 specificities.

Accompanying *in vitro* differentiation of foetal muscle and myogenic cell lines there was apparent loss of Thy-1 which was expressed on myoblasts but was not detectable by immunofluorescence on mature myotubes. This observation is consistent with lack of Thy-1 in adult muscle. The transitory appearance of Thy-1 on myogenic cells at the time of fusion and its absence on a non-fusing variant of the L6 myoblast line suggests that this antigen may be functional in normal muscle development. Glycoproteins bearing Thy-1 antigenic determinants have been purified from rat brain and thymus[2]. The chemical nature of Thy-1 antigen expressed in developing muscle is yet to be established.

The occurrence on myoblasts and immature myotubes of an antigen characteristic of thymocytes represents another unexplained association between muscle and thymus. Others include: (1) the presence of striated muscle ('myoid') cells as a constituent of normal mammalian, avian and reptilian thymuses[14]; (2) the presence in rat thymus of nicotinic acetylcholine receptors characteristic of muscle[15]; (3) the concurrence of pathological lesions in thymus and muscle in at least two spontaneous disease processes—myasthenia gravis and murine muscular dystrophy[16]; (4) the reported *in vivo* effect on neuromuscular transmission of thymopoietin, a putative thymic hormone which induces the expression of Thy-1 on cultured prothymocytes[17,18]. The possible function of an antigen shared by developing muscle and thymocytes, T lymphocytes and brain is open to speculation.

We thank Dr I. Trowbridge for anti-T25 antiserum and for performing the gel analysis of ATS specificity with iodinated surface proteins of mouse and rat thymocytes. We also thank Drs R. Hyman and D. Schubert for provision of cell lines and Ms J. Nieder for technical assistance. This work was supported by the Kroc Foundation, Santa Ynez, California and the Muscular Dystrophy Association.

Relationship between Na:K and Na:Na exchange by the sodium pump of skeletal muscle

THE sodium pump can catalyse several modes of cation exchange (for example Na:K, Na:Na, and K:K), which have been characterised mainly in human red blood cells[1-3], squid giant axon[4-6], and frog skeletal muscle[7-9]. In all three tissues it seems that intracellular ADP levels determine the extent to which the pump can engage in Na:Na exchange[2,6,9,10]. Yet, despite its obvious kinetic implications, the basic question of how the 'normal' Na:K exchange is affected by the appearance of ADP-induced Na:Na exchange, has not been answered. Here we present evidence that, in frog skeletal muscle, elevated intracellular ADP levels have little effect on pre-existing electrogenic Na:K exchange, but cause Na:Na exchange to appear in addition to ongoing Na:K exchange.

Frog sartorius muscles, which had been loaded with sodium and depleted of potassium by storage for approximately 48 h at 3 °C, were used. Previous work has shown that 2, 4-dinitrofluorobenzene (DNFB) is a metabolic inhibitor[11], raises intracellular ADP levels[9,12], and induces sodium pump-mediated Na:Na exchange in this preparation[9]. The experiments that follow show that DNFB does not appreciably alter Na:K exchange.

Strophanthidin-sensitive K influx was determined in muscles treated with DNFB to raise their ADP levels, and in controls. Figure 1 shows that elevation of ADP levels had only a small effect on K influx (there was little effect on either $V_{\max}$ or K_m). If Na:Na exchange, which we know to arise in such muscles (see ref. 9 and Fig. 2), actually took the place of Na:K exchange, then strophanthidin sensitive K influx should have been inhibited by induction of Na:Na exchange. There is no indication that this happened.

The sodium pump operates in markedly electrogenic fashion in sodium-loaded frog sartorius muscle fibres[14]. Thus, strophanthidin-sensitive membrane current can be used as another index of the extent of Na:K exchange, assuming that Na:Na exchange is electroneutral[1, 5, 9]. Table 1 lists measurements of membrane potential in a second series of sodium loaded muscles, bathed in 10 mM K low-chloride Ringer's. DNFB did not significantly alter ouabain-sensitive membrane potential or membrane resistance. We conclude, therefore, that elevation of ADP did not alter the current generated by the sodium pump, further evidence against enhancement of Na:Na exchange at the expense of Na:K exchange.

Table 1 Effect of DNFB on the ouabain-sensitive potential, and membrane resistance, of frog sartorius muscles

	Membrane potential (mV)	
	Control	DNFB-treated
Without ouabain	−67.7±1.6 (5)	−72.5±2.0 (5)
With ouabain	−49.3±2.1 (5)	−56.8±2.2 (5)
Ouabain-sensitive	18.4±2.6	15.7±2.9
	Membrane resistance (kΩ cm^2)	
	Control	DNFB-treated
Without ouabain	4.9±0.5 (4)	3.8±0.4 (4)
With ouabain	4.8±0.6 (4)	4.3±0.6 (4)

Values are means ± s.e.m. with the number of muscles indicated in parentheses. The difference in ouabain-sensitive potential between control and DNFB-treated muscles was not significant ($P > 0.2$), nor was the effect of DNFB and/or ouabain on membrane resistance ($P > 0.1$). Muscles were loaded with sodium by storage for 48 h at 3 °C in K-free Ringer's solution. Apart from this loading solution, all other solutions were low in chloride (10 mM) with isethionate used as a substitute. Low-chloride solutions were used to increase membrane resistance and to prevent the ouabain-induced membrane conductance increase described by Geduldig[15]. Washout of internal Cl from the muscle was by 3 h storage at 3 °C in K-free, low-Cl Ringer's Muscles were next equilibrated with K by storage, still at 3 °C, in 10 mM K, low-Cl Ringer's for 45 min. Muscles from 18 frogs were then exposed to 10 mM K, low-Cl Ringer's at room temperature, and muscles from another 18 frogs to a similar solution containing 0.38 mM DNFB. Of each muscle pair from the same frog, one member was exposed to 10^{-4} M ouabain as well. Membrane potential measurements were begun after 20 min and continued for another 20 min. (Since the DNFB effect peaks after 30 min exposure[9], this procedure bracketed the period of maximum Na:Na exchange.) Conventional 3M KCl-filled microelectrodes of approximately 3 mV tip potential and 20 MΩ resistance were used. Two microelectrodes we re-used to determine membrane resistance—one to pass current and the other to record steady-state membrane potential deflection. Input resistance and space constants were obtained from a semi-log plot of potential deflection against electrode separation. Membrane resistance could then be calculated by one-dimensional cable analysis, assuming internal resistance to be 169 Ω cm (ref. 16).

The above argument rests on a comparison made between separate batches of muscles, those used for K influx measurements compared with those used for Na influx measurements. A direct quantitative comparison of the two exchange mechanisms is therefore of value. Strophanthidin sensitive ^{22}Na influx (an index of pump-mediated Na:Na exchange) and strophanthidin-sensitive ^{42}K influx (an index of Na:K exchange) were measured in the same muscles. Figure 2 shows values for Na and K influxes in DNFB-treated and untreated muscles, with and without strophanthidin present. Strophanthidin-sensitive differences are plotted on the right. There is marked stimulation of Na influx (Na:Na exchange) but only slight inhibition of K influx (Na:K exchange). Assuming the pump's exchange rate to be 3:2 per turnover for normal Na:K exchange, and 3:3 when the pump is engaged in Na:Na exchange, then the observed K influx decrease of 1.6 μmol g^{-1} h^{-1} should result in the induction of just under 2.4 μmol g^{-1} h^{-1} Na influx by direct substitution. Since Na influx increased by 8.5 μmol g^{-1} h^{-1} it seems that a substantial amount of 'new' Na:Na exchange must have occurred in addition to ongoing Na:K exchange unless there is a vast difference in turnover rate between the two modes. The work of Garrahan and Glynn in red blood cells[1,2], as well as our own in frog muscle (unpublished) suggests that the turnover rate in the two modes is, in fact, comparable. (In addition, we have evidence that DNFB causes a 20% inhibition of the (Na+K)ATPase isolated from frog muscles, suggesting that some reduction of K influx could result from DNFB treatment, and that the actual discrepancy between Na influx 'gained' and K influx 'lost' may be even larger than observed here.) In any case, Na:K exchange is not much affected by elevation of ADP levels, despite marked stimulation of pump-mediated Na:Na exchange.

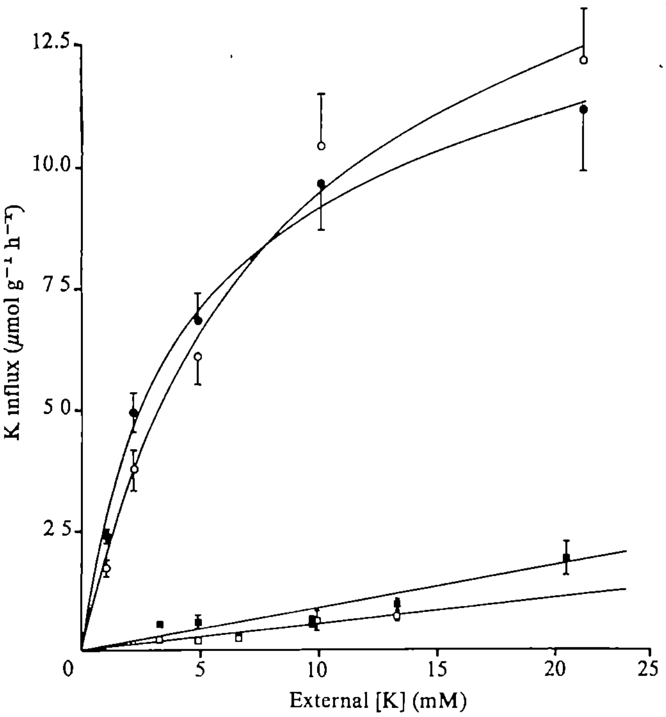

Fig. 1 Unidirectional K influx as a function of external [K] in DNBF-treated and untreated muscles. Values are means±s.e.m. □, ■, muscles exposed to 10^{-4} M strophanthidin; ○, ●, muscles not exposed to strophanthidin. Open symbols refer to muscles treated for 30 min with 0.38 mM DNFB; closed symbols refer to untreated muscles. The data obtained in the presence of strophanthidin were fitted by straight lines; the strophanthidin sensitive fluxes were fitted by rectangular hyperbolae. Muscles were stored in K-free Ringer's solution in the cold for approximately 48 h before the experiment. All solutions contained 5 mM Ba (hence the low level of strophanthidin-insensitive K influx)[13], and 10^{-7} g ml^{-1} tetrodotoxin to prevent twitching. K was elevated by substitution for Na, which was 115 mM in K-free Ringer's solution. Muscles were exposed to ^{42}K for 25 min (K influx is essentially linear for at least 1 h)[7] and total intracellular radioactivity was determined by back extrapolation to zero time of the linear portion of the washout curve. Parameters were: maximal influx, 10.92 ± 1.03 μmol g^{-1} h^{-1}, and K_m 3.19 ±0 73 mM, for control muscles; and maximal influx, 14.94 ±1.70 μmol g^{-1} h^{-1}, and K_m, 6.76±1.49 mM, for DNFB-treated muscles. There was a marginally significant effect of DNBF on both parameters ($0.05 > P > 0.02$).

To summarise, our experiments were designed to determine whether Na:Na exchange occurs in addition to, or in substitution for, ongoing Na:K exchange. We examined whether ouabain sensitive membrane potential and strophanthidin-sensitive K influx (both indices of pump-mediated Na:K exchange) could be inhibited by induction of Na:Na exchange, and found little evidence of inhibition. Our conclusion is that Na:K exchange can continue unaltered when Na:Na exchange is induced by the presence of ADP. This effect of intracellular ADP on the mode of operation of the sodium pump is in marked contrast to that of external potassium. Garrahan and Glynn[2] have shown in red blood cells that reduction of $[K]_o$ stimulates Na:Na exchange at the expense of Na:K exchange, and we have similarly found that raising $[K]_o$ to 10 mM reduces pump-mediated sodium influx into DNFB-treated skeletal muscle to low levels[17]. Further strong evidence in favour of interconvertibility of Na:K and Na:Na exchange is provided by the work of Bodemann and Hoffman[18].

The following qualitative kinetic picture of the sodium pump can now be drawn. In muscle cells with normal (that is, low) levels of ADP, bathed in K-free Ringer's solution, sodium

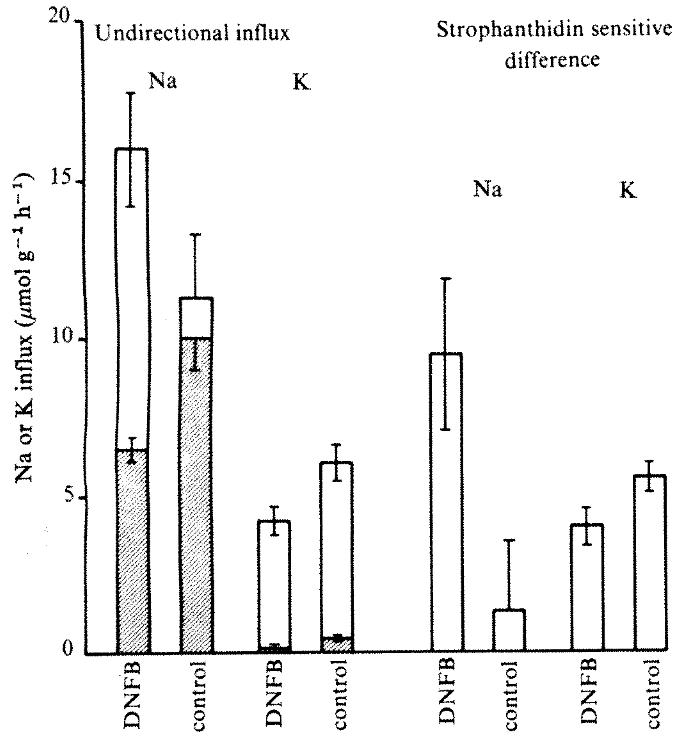

Fig. 2 Simultaneous determination of Na and K influxes. Values are means ± s.e.m. Protocol as for Fig. 1 except that both ^{22}Na and ^{42}K were present in the labelling solution, and that [K] was kept at 2.5 mM. At this [K], ouabain sensitive Na influx is reduced to about two thirds of its maximum value observed in K-free Ringer's. Hatched areas represent fluxes in the presence of 10^{-4} M strophanthidin. Washout samples were counted to determine total counts and then recounted after decay of the ^{42}K (more than 11 half lives). We found no long-lived contaminant in the ^{42}K used. Na influx values were not corrected for efflux during the uptake period, since the rate coefficient for efflux in DNFB is not constant[9]. Efflux is smaller in untreated muscles than in those treated with DNFB, however. Thus the strophanthidin-sensitive Na influx in DNFB will be underestimated (using the peak rate constant for efflux in DNFB, this underestimation was calculated to be about 20%) to a greater extent than that in untreated muscles. Consequently the stimulation of Na:Na exchange should, if anything, be even more pronounced than the uncorrected data suggest.

pump molecules are mostly inactive. As the external potassium concentration is raised, pump activity will increase toward saturation, thus reducing the silent fraction. At a given $[K]_o$, the silent fraction can be made to engage in Na:Na exchange to an extent determined by intracellular [ADP], while the previously active fraction continues to engage in Na:K exchange. Further elevation of $[K]_o$ in the presence of high intracellular ADP levels continues to recruit an increasing fraction of the pump population into Na:K exchange, but now at the expense of both the silent (if any) and the Na:Na exchanging fraction. Thus, induction of Na:Na exchange by ADP is additive with respect to ongoing Na:K exchange, as shown here, but induction of Na:Na exchange by removal of external potassium[2] is substitutive with respect to ongoing Na:K exchange.

Independent mechanisms of cyclic AMP and glucocorticoid action

IN eukaryotic cells, cyclic adenosine monophosphate (cyclic AMP) acts as the intracellular mediator for several hormones (for example, adrenaline and certain polypeptide hormones)[1] and plays an important part in the modulation of cell proliferation[2,3]. This cyclic nucleotide is known to function by activating a protein kinase[4,5] which mediates the phosphorylation of specific proteins, thereby modifying their biological activity. The activation of protein kinase may, in fact, be the sole mechanism of action of cyclic AMP in mammalian cells[6,7]. Glucocorticoids, and steroid hormones in general, act through a mechanism[8,9] which involves the binding of the hormone to specific cytoplasmic receptor proteins, the translocation of the receptor–steroid complex into the cell nucleus and the association with chromatin. The cellular responses to glucocorticoids and cyclic AMP are quite similar in several systems and the potentiating effect of the steroid on cyclic AMP-mediated processes is often referred to as 'permissive effect' (for reviews see refs 10 and 11). In several cell types glucocorticoids have been reported to increase, although moderately, the intracellular concentration of cyclic AMP (refs 12–15). These observations suggest that the cyclic nucleotide and glucocorticoids could have some distal step(s) in common in their mechanism of action. We have tested this hypothesis by cloning responsive cells in the presence of both effectors and report here that resistance to cyclic AMP and glucocorticoids occurs independently.

Our experiments were carried out with cultures of S49.1 mouse lymphoma cells in which both glucocorticoids and cyclic AMP (or its dibutyryl derivative, db cyclic AMP) inhibit cell proliferation and, on prolonged exposure, cause the cells to die[16–19]. Mutant cells resistant to growth-inhibitory and cytolytic effects have been isolated and most of them have defects related to known steps in the action mechanism of the two effector types[7,20–23]. One would therefore expect that most of the mutants of each type

Fig. 1 Dexamethasone binding in cytosol preparations of S49.1 clones. The clones (experiment of Table 2) grown in the presence of db cyclic AMP and dexamethasone (△, ▽) as well as representative clones from the other groups of plates (no selection, ●; selected in db cyclic AMP, ○; selected in dexamethasone, □) were grown up in suspension cultures. Cytosols were prepared and incubated with various concentrations of ^{3}H-dexamethasone (26 Ci mmol^{-1}, Amersham)[27]. The specifically bound steroid is plotted as a function of free steroid.

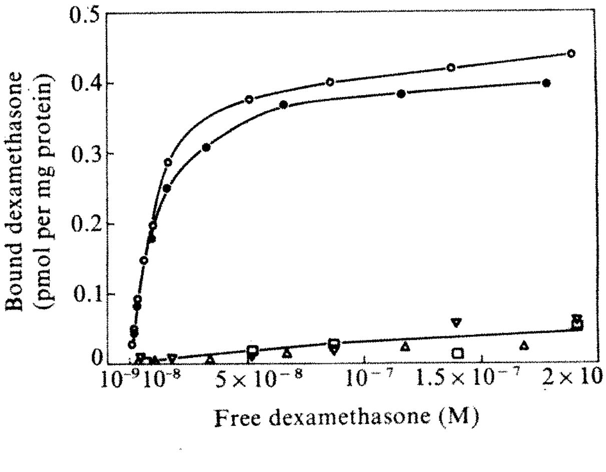

Table 1 Sensitivity of S49.1 clones isolated by single-step selection

Cloning in	Number of clones tested	Number of clones sensitive to Dexamethasone	db cyclic AMP
Dexamethasone	8	0	8
db cyclic AMP	20	20	0

S49.1 cells[14] were grown in Dulbecco's modified Eagles' medium supplemented with 10% foetal calf or horse serum and cloned over a feeder layer of mouse embryo fibroblasts[24,25] in soft agar containing 10^{-7} M dexamethasone or 0.5 mM db cyclic AMP and 0.2 mM theophylline. Clones were grown up and tested for sensitivity in suspension culture by seeding cells at a density of 3×10^5 ml^{-1} in medium containing either 10^{-7} M dexamethasone or 0.5 mM db cyclic AMP and 0.2 mM theophylline. After 3 d of incubation, cell viability was determined with Trypan blue at a concentration of 0.2%. Clones were designated sensitive if > 90% of the cells stained blue. At least 90% of resistant cells or cells incubated without drug excluded the dye.

should not show cross resistance. This is seen in Table 1 for several S49.1 clones which have been isolated by independent procedures. Since most glucocorticoid-resistant mutants carry defects in the steroid receptor[22,23], the possibility that the steroid receptor is involved directly in the response to the cyclic nucleotide is excluded. There could exist at a relatively low frequency, however, a subclass of mutants which differ from those described thus far and are defective in some mechanism common to both glucocorticoids and cyclic AMP. Such cells should be doubly resistant and should be selected preferentially if both agents were used together.

Table 2 shows a cloning experiment in which both the steroid and db cyclic AMP were used. Here the cloning efficiency was extremely low compared with cloning in the presence of either one of the agents; only two colonies were seen. Significantly, this incidence is nearly the product of the frequencies at which singly resistant clones occurred.

The most plausible explanation for this observation is that the 'doubly resistant' cells contain two independent mutations. These cell clones were therefore examined for the phenotypes of resistance. The cells of both clones were identified as deficient in glucocorticoid-specific receptors (Fig. 1). In extracts of these cells however, protein phosphokinase activity was stimulated by cyclic AMP in a manner indistinguishable from the wild type (data not shown). Growth experiments in suspension cultures revealed that the two clones obtained in the double selection experiment of Table 2 were still growth inhibited by the cyclic nucleotide (Fig. 2). The half-maximum effect was between 0.05 and 0.1 mM db cyclic AMP (data not shown). Consistent with this growth inhibition, these clones appeared as very small colonies in the experiment of Table 2 and would probably not have been picked for further propagation in a single selection experiment in which a fair number of more highly resistant mutants with defects in protein kinase are routinely recovered[25]. The preferential accumulation of cells in the G_1 phase of the cell cycle was observed by flow cytometry[28] on exposure of the mutant cells to the cyclic nucleotide (data not shown). While 0.3 mM db cyclic AMP completely arrested wild-type cells in G_1 after 24 h (ref. 17), the effect on the mutant cells was less pronounced. This is consistent with the intermediate growth inhibition (Fig. 2). These growth characteristics and the presence of cyclic AMP-responsive phosphokinase show phenotypic similarities between these mutant clones and the recently isolated cyclic AMP unresponsive 'deathless' cells[29]. These 'deathless' mutants are growth inhibited, but not lysed, by cyclic AMP, however, they are fully sensitive to steroid-induced cytolysis.

Table 2 Incidence of resistance to dexamethasone and db cyclic AMP

Agent present during cloning		Cells applied per plate	Colonies grown per plate	Mean frequency of resistant cells*
Dexamethasone	db cyclic AMP			
–	–	10^2	45, 50, 53	
+	–	10^4	22, 24, 27	5.0×10^{-3}
–	+	10^6	45, 49, 52	9.9×10^{-5}
+	+	10^6	1,1,0,0,0, 0,0,0,0,0	4.1×10^{-7}

*Corrected for plating efficiency of 49%.

Recently cloned S49.1 cells were treated for 24 h with 0.75 µg ml^{-1} ICR 191 (a gift from Dr H. R. Creech). Surviving cells were allowed to grow up in the absence of drugs and were used for the cloning experiment (compare with Table 1). Plates with additions contained dexamethasone at 10^{-7} M and 0.5 mM db cyclic AMP plus 0 2 mM theophylline. The expected frequency of doubly resistant mutants is $5.0\times10^{-3}\times9.9\times10^{-5}=5.0\times10^{-7}$ if each marker is acquired in a distinct and independent step[26].

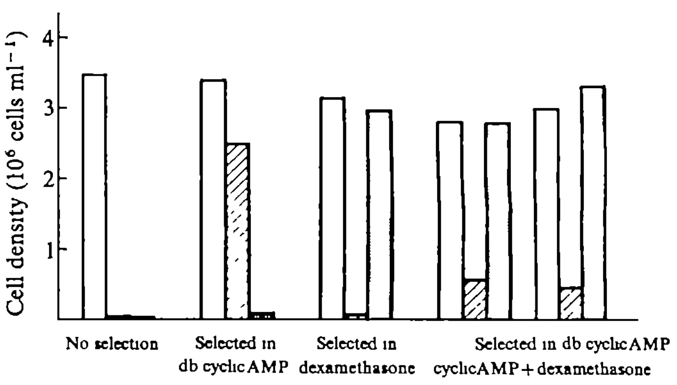

Fig. 2 Growth of S49.1 clones in the presence of db cyclic AMP and dexamethasone. Clones from the experiment of Table 2 (the same as used for Fig. 1) were grown in suspension culture and seeded at a cell density of 2×10^5 ml^{-1} in medium containing either 10^{-6} M dexamethasone (stippled bars) or 0.5 mM db cyclic AMP and the phosphodiesterase inhibitor RO 20-1724 at a concentration of 30 µM (hatched bars). The density of viable cells was determined after 72 h. Control cultures are represented by open bars.

The experiments described here indicate two independent lesions for steroid resistance and decreased cyclic AMP sensitivity, respectively, in the 'doubly resistant' mutants. This implies that there is no common mutable biochemical step in the two processes from effector–cell interaction to cytolysis in the cell system studied here. We cannot exclude, however, the possibility that mutations in a biochemical process common to cyclic AMP and steroid-mediated cytolysis occur at a frequency too low to be detected by our technique. Alternatively, such a common biochemical process could be required for cell viability. If so, mutations affecting that putative process would result in cell death and mutants could therefore not be obtained, except as conditionally lethal mutants. Nevertheless, there is synergism between cyclic AMP and glucocorticoids in S49.1 lymphoma cells. If these cells are pre-exposed to db cyclic AMP and thereby arrested in the G_1 phase of the cell cycle they are much more susceptible to the cytolytic effect of the steroid than untreated cells[18]. There must therefore exist, at some level, interaction between both effector systems in these cells as well as possibly in other mammalian cells.

The shape of the ultraviolet inactivation curve for transforming DNA

THE very unusual inverse square kinetics of ultraviolet inactivation of transforming DNA were first reported by Rupert and Goodgal[1], and subsequently there was speculation that these kinetics result from blocks to recombination formed by ultraviolet lesions in the DNA[3] (ref. 2). We show here that when the recipient cell lacks both excision and postreplication repair, the ultraviolet inactivation of transforming DNA becomes a simple exponential rather than an inverse square relation. The data suggest that the square root kinetics observed with repair-proficient recipient cells result from repair processes themselves rather than from the recombination between irradiated transforming DNA and recipient DNA.

The inverse square relation, shown for transforming DNA from *Haemophilus influenzae*[1] and *Bacillus subtilis*[2], is: $\sqrt{(N_0/N)}=1+CD$, where N_0 and N are the number of transformants from unirradiated and irradiated DNA, respectively, D is the dose and C is a constant which depends on the genetic marker, the particular DNA preparation, the wavelength of the radiation and the repair capacities of the host[1,3,4]. The equation fits the data except for very large doses, where the inactivation becomes close to exponential[5]. Two theoretical formulations for the inactivation of transforming DNA have been based on the idea that recombination of a piece of DNA can take place up to but not including an ultraviolet lesion[2,6] After the first increment of dose, the 'targets' for further inactivation are the sections of DNA molecules between the genetic marker and the nearest lesion. Further inactivation takes place only when a lesion occurs in one of these sections. Thus with increasing dose the target decreases in size, and a larger and larger increment of dose is necessary for further inactivation. The theoretical formulations, although slightly different, both approximate to the empirically obtained equation[1], but are based on an incorrect assumption, namely that pyrimidine dimers in transforming DNA, responsible for almost all the inactivation by ultraviolet radiation[5,7], are not integrated into the recipient genome. It was first shown that dimers are integrated into *H. influenzae* recipient DNA by a demonstration that irradiated transforming DNA which was integrated by the criterion of marker linkage could be enzymatically photoreactivated[8]. It was later found that integrated DNA containing dimers can kill the recipient cell[9], and that excision of dimers takes place only after the damaged DNA has been integrated[10–13].

Excision repair might be considered to be responsible for the square root relationship, with the following rationale. Because transforming DNA is integrated into the recipient genome as a single strand[14], there is a finite probability that excision repair not only may eliminate damage, but may also eliminate the genetic marker assayed in transformation. Following a given increment of dose, whether the repair process eliminates the marker or helps the marker to survive depends on the distance between the marker and the nearest ultraviolet lesion (usually a pyrimidine dimer), and also on the length of the region excised, assumed to be variable from one repaired region to another. After a second increment of dose, the only transforming DNA molecules with a still lower probability for transformation are those with an ultraviolet lesion between the marker and the previous lesion. But, excision repair alone cannot provide the explanation for the shape of the inactivation curve for transforming DNA, since the square root relationship also holds for recipients that are lacking in excision ability[4,15,16].

It has been suggested that postreplication repair might be the cause of some loss of donor genetic information, and thus be responsible for the shape of the inactivation

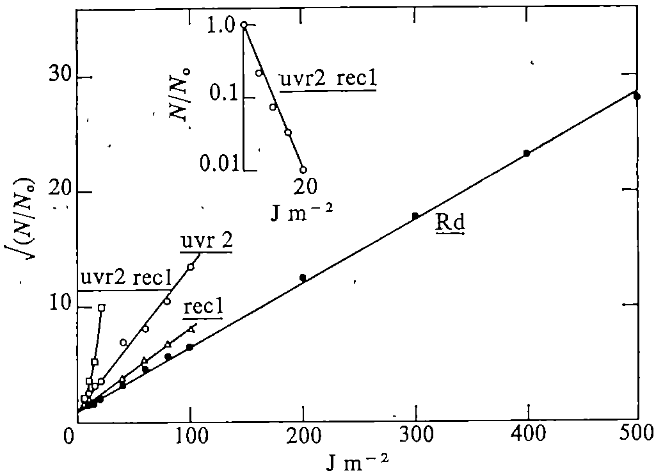

Fig. 1 Inactivation of transforming DNA assayed on four different streptomycin-sensitive *H. influenzae* strains, *Rd* (wild type), *recl-1* (ref. 20), *uvr2* and *uvr2recl* (ref. 21). N and N_0 are the number of transformants obtained from irradiated and unirradiated DNA. Transforming DNA from cells resistant to 250 μg ml^{-1} streptomycin was purified as previously described[22] and irradiated at 10 μg ml^{-1} in 0.15 M NaCl plus 0.015 M trisodium citrate. Irradiation at 254 nm was performed as before[4]. Cells were made competent by a modification of Stuy's method[23]. They were grown with aeration in supplemented brain heart infusion medium[4] to an optical density of 0.44 at 675 nm, and then left standing at 37 °C for 90 min without aeration They were then diluted a factor of eleven into 10 mM phosphate buffer, *p*H 7.0, plus 0.15 M NaCl, and shaken at 30 °C for 60 min. They were next exposed to 1 μg ml^{-1} transforming DNA at 37 °C for 30 min. Growth medium (2 to 5 ml) was then added to each 1 ml of cells, and the cells were grown for 2–3 h before being plated in streptomycin-containing agar medium. The larger volume was used for the *recl* strains, in order to obtain statistically significant numbers of transformants, and ten platings of 1 ml each were made for each point. Each of these assays (all obtained with the same set of irradiated DNAs) were repeated at least three times and the data averaged. The minimum number of *recl* or *uvr2recl* colonies counted per point was 70. The approximate frequencies of transformation by unirradiated DNA in these experiments were 0.7×10^{-2} (*Rd*), 0.5×10^{-2} (*uvr2*), 0.5×10^{-7} (*recl-1*) and 0.2×10^{-7} (*uvr2recl*).

curve[14]. Postreplication repair in *H. influenzae* has been shown to involve extensive exchange between new and old strands[17], during which the transforming DNA marker integrated into only one strand could be eliminated with a probability dependent on the distance between the marker and the nearest lesion, and on the (variable) length of the exchange. A test of the hypothesis is to measure the survival of irradiated transforming DNA on a mutant strain such as *recl* (ref. 18) deficient in postreplication repair[17,18]. Earlier attempts at this experiment were defeated by the extremely poor transformation of the mutant (around 10^{-6} the frequency of the wild type). Recently it has been found that with a different competence regime, the transformability of the *recl* strains, but not other strains, is markedly improved[20], making the measurement feasible.

Figure 1 shows data plotted in the square root plot for ultraviolet inactivation of transforming DNA assayed on four different *H. influenzae* recipients. The data on three of the recipients, the wild-type (strain *Rd*), postreplication repair-deficient *recl* and excision-deficient *uvr2*, fit the straight line relationship, whereas on the double mutant *uvr2recl* recipient the data deviate from the straight line. Moreover, the transforming DNA assayed on *uvr2recl* seems to be inactivated exponentially, as seen in the insert of Fig. 1.

I interpret the data to mean that excision and/or postreplication repair in the recipient is responsible for the inverse square relationship. When repair is absent the inactivation becomes exponential, as though there is a critical region of DNA surrounding the marker which must be free of damage for transformation to be successful.

Excision repair increases survival of transforming DNA more than does postreplication repair, as seen in the fact that the DNA assayed on *recl* seems only a little more sensitive than on the wild-type strain *Rd*, but on *uvr2* the DNA seems considerably more sensitive. Postreplication repair in *H. influenzae* is not an inefficient process, as judged by its effect on survival following ultraviolet irradiation of cells[21]. Thus postreplication repair may eliminate the transforming DNA marker almost as often as it increases its survival.

This research was carried out at Brookhaven National Laboratory under the auspices of the US ERDA.

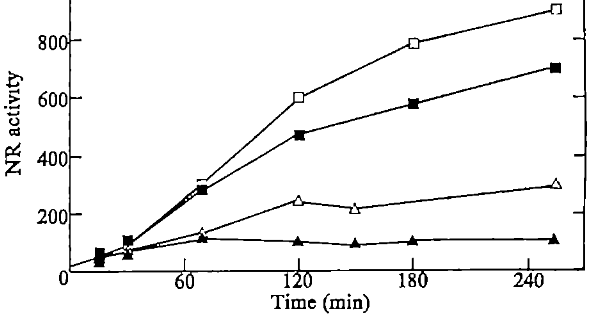
Psoralen and near ultraviolet light; a probe for study of control of protein synthesis

THE study of the control of protein synthesis in eukariotic cells usually involves the use of chemical inhibitors of macromolecule synthesis[1]. The drawback of these procedures is that the inhibitors have side effects which do not allow conclusive interpretations. Furthermore, the precise timing of the inhibitor effect is not always possible due to the lack of knowledge of the effective *in vivo* concentration and the rate of its entry into the cells. Furocoumarins (psoralens) photosensitise biological systems to near ultraviolet (NUV) light (300–400 nm) (refs 2–4). Psoralen and its derivatives react with pyrimidine bases in DNA when irradiated with NUV light to form monoadducts and DNA crosslinks[5,6], the latter being the main lesion responsible for the biological damage in bacteria and mammalian cells[4,7]. Since the photoreactions in the cells are specifically with DNA[8,9] and lead to its immediate inactivation as a template for DNA and RNA synthesis[9], we have considered the use of this system for the study of control of protein synthesis. The degree of inactivation of DNA can be easily controlled by varying the NUV light dose, thus avoiding the complications involved in the use of drugs.

The well documented[10] development of nitrate reductase (NR) activity in the XD cell line of tobacco, in response to nitrate, was chosen as the system under study. The cells were grown as previously described[11] on chemically defined, nitrate-less M-ID medium supplemented with 5 mM L-glutamine (Gln cells) as a sole nitrogen source. Cells were grown to mid-logarithmic phase, collected by filtration and resuspended in fresh nitrate-less M-ID medium at 1 g per 10 ml. 4,5′8-trimethylpsoralen (Paul B. Elder Co.) was added to a final concentration of 5×10^{-6} M. The cells were incubated in the presence of psoralen for 5 min, and then irradiated for the indicated duration with two tubular fluorescent black light lamps (UV Products, lamp 50058) held in a reflector. Maximum emission of the lamps was at about 360 nm and the incident flux was 20 J m^{-2} s^{-1} as measured by a calibrated black light meter (Model J-221, UV Products). During irradiation, the cell suspensions were continuously stirred. At the end of the irradiation period, samples of the cell suspensions were removed and were either diluted into nitrate-less M-ID medium supplemented with 10 mM KNO_3, or kept undiluted and given KNO_3 to a final concentration of 10 mM, when induced, or non-induced cells were used, respectively. Cells not treated were used as control. Following irradiation, the cells were shaken for the duration of the experiment. The NR activity *in situ* was determined at time intervals by the procedure described by Ferrari *et al*[12]. Enzyme activity is expressed as nmol NO_2^- formed per h per g fresh weight.

The effect of psoralen + NUV light on the induction of NR activity induced by nitrate in Gln cells is shown in Fig. 1. Increasing the radiation dose reduced the rate of develop-

Fig. 1 The inhibitory effect of psoralen plus NUV light on the induction of NR activity. Cells were grown in nitrate-less M-ID medium supplemented with 5 mM L-glutamine. The cells were collected and resuspended in nitrate-less M-ID. KNO_3 (10 mM) was added to part of the cell suspension and used as control (□). The rest of the cell suspension was exposed to psoralen (final concentration 5×10^{-6} M) and irradiated for 1 min (■); 3 min (△), and 5 min (▲). KNO_3 was added to the treated cells (final concentration 10 mM) at the end of the irradiation period. The NR activity *in situ* was determined at the indicated times.



ment of NR activity and markedly lowered the steady state level of the enzyme. The two effects could be observed as early as 15–30 min after exposure of the cells to nitrate. There was no effect of either psoralen alone or irradiation alone (data not shown). Only the combination of psoralen and NUV light at the proper dose was inhibitory to the development of enzyme activity.

The effect of psoralen plus NUV light on partially induced cells is shown in Fig. 2. Irradiation for 1 min strongly inhibited further development of the enzyme as compared with control cells. Higher radiation doses caused the initial level of activity to decline in time.

Based on the target specificity of psoralen plus NUV light[8] we interpreted the results shown in Figs 1 and 2 as follows. Exposure of cells to psoralen plus NUV light just before nitrate addition (non-induced cells) or during the induction process (induced cells) inhibits the synthesis of functional mRNA, thereby inhibiting the development of NR activity. We further suggest that in cells growing on L-glutamine as a nitrogen source there is none or very little mRNA coding for the NR protein complex or for an essential subunit of the enzyme. If mRNA coding for the enzyme were present in Gln cells one would expect an initial development of NR activity upon exposure of the cell to nitrate, which is insensitive to the effect of psoralen plus NUV light. The inhibitory effect of psoralen plus NUV light would be observed gradually as old mRNA decays and the synthesis of new mRNA is inhibited. Such a situation is summarised in Fig. 3. It was previously shown[13] that tungsten (W), an analog of molybdenum (Mo), inhibits the development of NR activity in XD cells due to the formation of non-functional enzyme. The non-functional enzyme can be made functional to a certain extent *in vivo* in the absence of protein synthesis (presence of cycloheximide) by adding excess Mo. Thus, it was assumed that the mRNA present in W-treated cells and translated to a non-functional enzyme, would be translated to a functional enzyme following exposure to psoralen plus NUV light and addition of Mo. It can be seen from Fig. 3 that this was indeed the case. The low level of NR activity in cells which were treated with W increased following exposure to psoralen + NUV light and addition of excess Mo. The increase cannot be accounted for by the activation of pre-existing non-functional enzyme, as can be judged by cells treated with cycloheximide before the addition of Mo.

We conclude that exposure to psoralen plus NUV light inhibits the synthesis of mRNA coding for NR or an essential subunit of the enzyme, thereby inhibiting the synthesis of the enzyme. The translation of pre-existing mRNA is not affected. We suggest that the combination of psoralen and NUV light can be used to distinguish between transcriptional and post-transcriptional controls of protein synthesis.

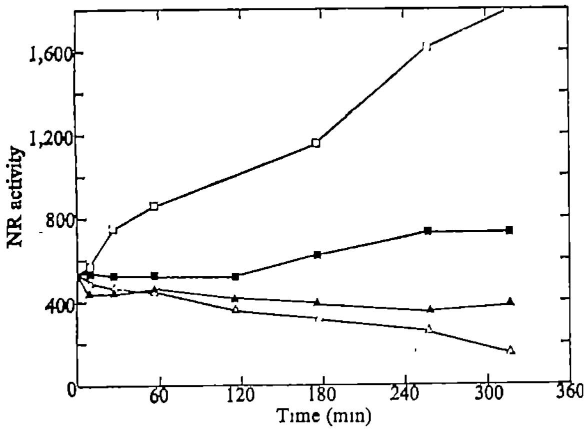


Fig. 2 The effect of psoralen plus NUV light on NR activity of partially induced cells. Cells were allowed to develop NR activity for 24 h and were then collected and treated as described in Fig. 1. Control (□), 1 min irradiation (■), 3 min irradiation (▲), 5 min irradiation (△).

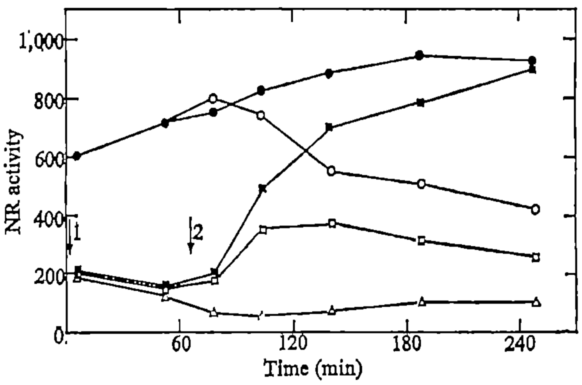

Fig. 3 Translation of pre-existing mRNA following exposure to psoralen plus NUV light. Cells were allowed to develop NR activity in the absence (●, ○) and presence (■, □, △) of 2×10^{-4} M sodium tungstate. At zero time, arrow no. 1, cycloheximide was added to one of the cell suspensions (△) to a final concentration of 10 μg ml^{-1}. Arrow no. 2 indicates: first, exposure of the cells to psoralen plus 5 min irradiation (○, □), and second, the addition of sodium molybdate to a final concentration of 2×10^{-4} M to all of the cell suspensions (●, ○, ■, □, △). At the indicated times NR activity *in situ*, was determined.

We thank Miss Michal Zeitun for technical assistance.

Genetic recombination through protoplast fusion in *Streptomyces*

MEMBERS of the genus *Streptomyces* yield over 60% of known antibiotics[1], including more than 70 commercial products[2], as well as at least one very important enzyme (glucose isomerase). Members of the related genera *Nocardia* and *Micromonospora* produce some further valuable antibiotics (rifamycins, gentamicins). Recombination through conjugation is widespread in these actinomycetes[3] but only to a very limited extent has it been applied to strain improvement. The main reason for its neglect has probably been the necessity to introduce selectable (for example drug resistance) or more generally counter-selectable (auxotrophic) markers into the strains to be crossed in order to identify recombinants occurring at frequencies of 10^{-6} or lower among predominantly asexual progeny. The marking of strains is time-consuming; moreover it may induce deleterious mutations along with the markers, and these will usually go undetected since auxotrophic mutations themselves often depress antibiotic yield. In certain cases, recombination occurs so rarely that single markers in each parent cannot be used to distinguish it from reverse mutation[4], while in some strains

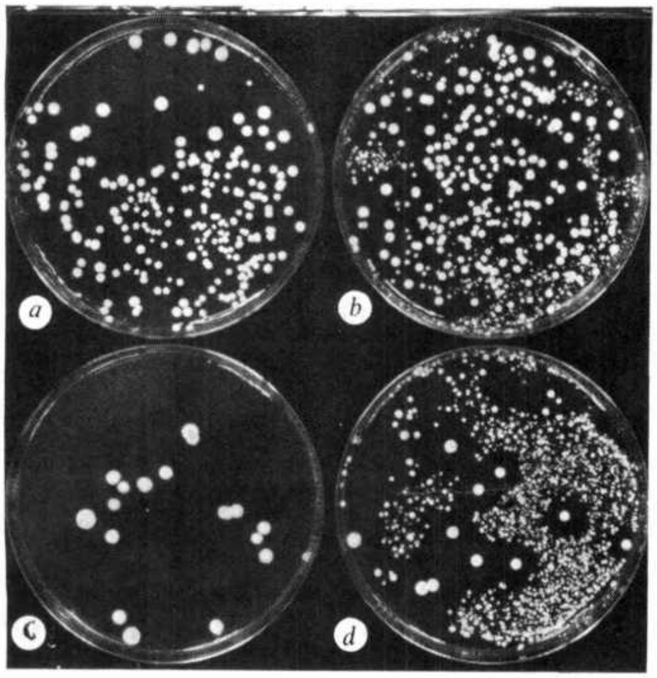

Fig. 1 Platings of *S. acrimycini* protoplasts on regeneration medium after dilution in water (*a*, *c*) or medium P (*b*, *d*) at dilutions 10^{-1} (*a*, *b*) and 10^{-2} (*c*, *d*). Note the large colonies derived from osmotically stable non-protoplasted units, occurring in equal numbers on both series of plates, and the much more numerous colonies arising from regenerated protoplasts after dilution in medium P. The latter are severely inhibited, especially at lower dilution, by the precociously developing non-protoplast colonies.

no recombination has been detected[3]. The availability of a simple generally applicable procedure to recombine actinomycete strains at high frequency would therefore greatly facilitate the routine use of recombination in strain improvement. We report here such a procedure for *Streptomyces* which depends on polyethylene glycol (PEG)-induced protoplast fusion and regeneration. Recombination frequencies achieved by this technique are so high that selectable markers could be dispensed with, at least in certain kinds of strain improvement programmes.

Protoplasts of five species were prepared and regenerated by procedures slightly modified from those of Okanishi, Suzuki and Umezawa[5]. 25 ml samples of medium S containing 1–4% glycine, depending on the strain, were inoculated with 10^7–10^8 spores and incubated with shaking in 250 ml Erlenmeyer flasks at 30 °C for 3–4 d. Growth was progressively retarded, and the efficiency of conversion of mycelium to protoplasts increased, with increasing glycine concentration. For routine protoplast preparation, mycelium was therefore collected from flasks with a glycine concentration which markedly inhibited growth but which allowed a reasonable yield of mycelium. After two washes at room temperature with 0.3 M sucrose, mycelial pellets (usually consisting of spherical aggregates about 1 mm in diameter) were re-suspended in 1.5 ml of lytic enzyme mixture and incubated at 32 °C until clouds of protoplasts were liberated from the mycelial mass on gentle swirling of the liquid (60–90 min). 4 ml of medium P was added; the suspension was pipetted vigorously several times to aid release of protoplasts from the still largely coherent mycelial mass, and filtered through cotton wool (sometimes followed by Nucleopore filtration). The protoplasts were pelletted by centrifugation at 1,000*g* for 5–10 min, resuspended in 4 ml of medium P and again pelletted and resuspended.

For studies of protoplasting and regeneration efficiency, samples of the suspensions were diluted in parallel in medium P (which contains 0.3 M sucrose) or in water and plated on R2 regeneration medium supplemented with required growth factors. (In preliminary work, the R1 and R2 media[5] were assessed; somewhat higher regeneration frequencies were obtained with R2 and this was therefore adopted.) Colonies from water-diluted suspensions arose from osmotically stable and presumably non-protoplasted units (mycelial fragments produced by sonic disruption of control cultures equilibrated in medium P were 100% osmotically stable), while the excess of colonies from comparable dilutions in medium P represented regenerated protoplasts. For some strains, non-protoplasted units developed precociously so that colony counts after dilution in water or medium P were at first the same; later, numerous protoplast colonies appeared on the plates that received osmotically protected suspensions. In most strains the protoplast colonies soon reached the size of the non-protoplast colonies. In *S. acrimycini*, however, non-protoplast colonies inhibited development of the protoplast colonies, which were largely suppressed on high-density plates (Fig. 1). Non-protoplasted units typically represented 0.1–1% of total colony-forming units when the parent culture was grown with an optimal glycine concentration. With lower concentrations, the proportion was higher; it was essentially unchanged by filtration through 2.1-μm Nucleopore filters after the routine cotton-wool filtration and so this step was usually omitted. Protoplasts varied so greatly in size, many possibly being too small to contain a genome, that little confidence was placed in microscopic counts; rough estimates of regeneration frequency were lower than the maximum of 40–50% reported by Okanishi *et al.*[5].

Protoplast fusion induced with PEG has been described in bacilli[6,7] but we closely modelled our procedure on that of Pontecorvo, Riddle and Hales[8] for animal cells. Equal volumes (0.5–2 ml: half to a fifth of the yield of a flask) of protoplast suspensions of the two strains were mixed and, after centrifugation, the pellet was thoroughly drained and rapidly suspended in 0.5 ml of PEG 1540 1w+1.4 volumes medium P containing 15% dimethylsulphoxide (DMSO). After 1 min, 0.5 ml of PEG 1w+3 volumes of medium P was added and, after a further 3 min, 4 ml of medium P. Control pellets were suspended in 5 ml of medium P. The suspensions (containing flocculent protoplast aggregates after PEG treatment) were centrifuged, each pellet was resuspended in 0.25 ml of medium P, and the liquid was poured over a single plate of R2 medium supplemented with all growth factors required by both parental strains. Gentle spreading of the suspensions was done with a loop, rather than a glass spreader which might have tended to disrupt protoplast aggregates. After incubation of the plates for 4–6 d, spores were collected from the confluent cultures and assayed for parental and recombinant genotypes by standard procedures[9].

For four species, *S. coelicolor*, *S. lividans*, *S. parvulus* and *S. griseus*, recombinants recovered on a medium selecting markers at two loci represented 1–27% of the frequency of the minority parental class, and 1–6% of the sum of both parentals (Table 1). In *S. coelicolor* A3(2), the same high recombinant frequency occurred in the absence of both known sex factors, SCP1 and SCP2 (ref. 10), as in the presence of one (Table 1) or both, suggesting that the recombination occurring following protoplast fusion is independent of sex factor activity and should therefore occur even in wild types that lack sex factors. In *S. acrimycini*, the recombination frequency was only 3×10^{-4}, but this is readily explicable by the inhibition of protoplast by non-protoplast colonies (see above; Fig. 1); a minority of the latter contributed disproportionately to the total spore progeny on the regeneration plates. There was little or no evidence for significant spontaneous protoplast fusion

Table 1 Recombination in five streptomycetes

Strains*	Treatment	Recombinants per minority parent	per majority parent	per total
S. coelicolor A3(2)	Mating	1.0×10^{-4}	1.8×10^{-6}	1.7×10^{-6}

	(PEG)	5.3×10^{-4}	4.9×10^{-4}	2.6×10^{-4}

Compositions (quantities per litre of final medium) of medium S (for mycelial growth), medium P (for protoplast formation) and R2 (for regeneration) were as follows[5]. Medium S: glucose, 10 g; Difco Bacto peptone, 4 g; Difco yeast extract, 4 g; $MgSO_4.7H_2O$, 0.5 g; KH_2PO_4, 2 g; K_2HPO_4, 4 g. Glycine was added to medium S at 1% for *S. coelicolor* and *S. lividans*, 1.5% for *S. parvulus*, 2.5% for *S. acrimycini* and 3.5% for *S. griseus*. Medium P: sucrose, 103 g; K_2SO_4, 0.25 g; $MgCl_2.6H_2O$, 2.03 g; trace element solution (per litre: $ZnCl_2$, 40 mg; $FeCl_3.6H_2O$, 200 mg; $CuCl_2.2H_2O$, 10 mg; $MnCl_2.4H_2O$, 10 mg; $Na_2B_4O_7.10H_2O$, 10 mg; $(NH_4)_6Mo_7O_{24}.4H_2O$, 10 mg), 2 ml; †KH_2PO_4 (0.5%), 10 ml; †$CaCl_2.2H_2O$ (3.68%), 100 ml; †TES buffer (0.25 M, *p*H7.2), 100 ml. Medium R2: sucrose, 103 g; K_2SO_4, 0.25 g; $MgCl_2.6H_2O$, 10,12 g; trace element solution, 2 ml; glucose, 10 g; Difco casaminoacids, 0.1 g; Difco Bacto agar, 22 g; †KH_2PO_4 (0.5%), 10 ml; †$CaCl_2.2H_2O$ (3.68%), 80 ml; †L-proline (20%) 15 ml; †TES buffer (0.25 M, *p*H 7.2), 100 ml.

†Added after autoclaving.

since recombination frequencies were similar in mixtures of protoplasts untreated with PEG and in standard crosses ('matings') made on supplemented R2 medium (Table 1); mating after regeneration could therefore have accounted for the results. A possible exception was *S. coelicolor* A3(2) in SCP1$^-$ SCP2$^-$ condition in which recombination in matings occurs at very low frequencies[10].

In studies of mammalian cells[11,12], DMSO has been found to shift the optimal PEG concentration for fusion from 50% to 40%, allowing the use of a less viscous reagent; this advantage, important for high molecular weight PEG, may be marginal with low molecular weight PEG (such as the 1,540 tested here). With SCP1$^-$ SCP2$^-$ mixtures of *S. coelicolor* A3(2), we tested the effect of omitting DMSO, with or without an increase in PEG concentration from the standard 40% to 50%. At 40% PEG, DMSO caused a significant increase in recombination frequency, but this was largely compensated by raising the PEG concentration to 50%. These findings were strikingly comparable with those for mammalian cells Since the standard procedure was consistently as good as or better than the variations on it, we saw no reason to depart from it.

Analysis of the segregation of non-selected markers amongst recombinants from six-factor crosses of *S. coelicolor* A3(2) derivatives (SCP1$^-$ SCP2$^+$ × SCP1$^-$ SCP2$^+$ or SCP1$^-$ SCP2$^-$ × SCP1$^-$ SCP2$^-$) was done by selecting recombinants inheriting markers at two loci on opposite sides of the circular linkage map with two non-selected markers in each half of the linkage map to divide each half into three approximately equal map intervals. In a mating, multiple crossover classes represented about 2% of total progeny, but after protoplast fusion they represented over 20%. This loosening of linkage (increased recombination per unit of map length) might in part reflect a more complete diploidy in the units produced by protoplast fusion than in the merozygotes arising by mating; another possible explanation is multiple rounds of recombination in the large units arising by multiple protoplast fusion and regeneration (an enormous increase in protoplast size was described[5] before regeneration).

The technique described here should be useful in at least some recombinational approaches to industrial strain improvement. Particularly important are the very high recombination frequencies achieved, even in the absence of detectable sex factor activity. a frequency of 6% recombinants inheriting one of two alleles at each of two loci is equivalent to a total 'sexual' progeny of 24%. Moreover, the observed linkage relaxation would lead to a much more nearly random assortment of genotypes in a cross than would normally be the case. Both features would be ideal in the crossing of divergent lines obtained by successive mutant selection in order to generate an assortment of new genotypes, including those in which positive gene interactions gave rise to superior performance, or in which groups of negatively interacting genes had been disrupted[13]. Once recombinant yields had been optimised for a given set of strains, by minimising contamination of protoplasts with non-protoplasted units and by equalising the frequencies of the two parental genotypes, the total non-selected progeny of protoplast fusion could be screened for desirable phenotypes without the need for selectable markers When two parents differ by several mutations, the great majority of 'sexual' progeny are recombinant in respect of these mutations. Even with a comparatively modest total frequency of such progeny of 10%, the percentage of unimproved genotypes in the protoplast fusion procedure could be less than that of unimproved and disadvantageous genotypes which survive a typical mutational step in strain improvement.

Other potential contributions of the procedure to *Streptomyces* genetics would be in the synthesis of genotypes carrying combinations of known markers. A limiting step in the development of genetics in a new strain is the production of multiply-marked stocks by the successive induction of mutations, usually auxotrophs. In matings, two auxotrophic markers are lost by counter-selection whenever two lines are combined and at least three different markers are needed in each parent before recombinants can be selected carrying more markers than either parent. By protoplast fusion, the markers of two parents can be combined without loss, allowing the rapid construction of complex genotypes. Whether or not the technique described here can be applied to the other important genera of actinomycetes, and to interspecific combinations, remains to be seen.

We thank Professor G. Pontecorvo for advice in the choice of conditions for PEG treatment. S.N.C. acknowledges a grant from the Josiah Macy Jr Foundation to enable him to spend a period at the John Innes Institute.

Test of the ballistic hypothesis of movement and the 'point of no return'

How long does it take to stop or modify a movement once it has begun? Where there is an error in producing an action as intended (usually because of control-display incompatibility) subjects may correct it in less than their normal reaction time (RT) by proprioception[1] or efference-copy monitoring[2–4]. Where subjects work from a visual (external) error signal, however, they are usually said to take a full RT to stop[5] or correct[6,7] ongoing movements, so that there is a 'point of no return', after which they are committed for about 300 ms to any action decided on[8]. During this time the action is ballistic at the perceptual-motor level[8,9,10]. But in a recent tracking experiment[11] where subjects wrongly anticipated the target motion, and so began a movement in the wrong direction, the correction time to stop the action (CorT) was often much shorter than the normal RT to initiate movements, down to as little as 120 ms in some cases. This suggests that fast error correction can occur from a visual signal alone, at least to stop movements (as in an emergency). Repeating the experiment we find that movements can indeed be arrested soon after they begin, but only if the beginning is delayed; it always takes one RT from the occurrence of the error signal. We therefore infer that there is a 'point of no return' at the decision level, but that movements are not necessarily ballistic at the motor level.

The experiment requires subjects to track predictively a target moving in a regular sequence of steps. They are told to try to synchronise their movements with those of the target, and thus to begin their actions at about the time they anticipate it will move. The target is then occasionally made to jump in the direction opposite to that expected, and the time taken to stop wrongly-predicted movements at these 'surprise jumps' (SJs) measured. As control and display are compatible, the only error signal is visual, and CorTs for incorrect movements are directly comparable with both normal RTs and RTs for correct movements at SJs (where subjects do not make errors).

Fifteen students were tested using an oscilloscope display and joystick control (described elsewhere[11]). The 3-mm target circle jumped horizontally from the centre of the screen to points 30 mm to left or right, and back, pausing for about 2 s at outward points and 1 s in the centre. There were seven trials of 20 cycles (120 s) each. On trials 1 and 7 the pattern of jumps outwards from the centre was irregular, and subjects followed the target as quickly as possible. On all other trials the target jumped alternately left and right (except where SJs occurred in trials 4, 5 and 6). On trials 2 and 6 subjects followed the target; on trials 3, 4 and 5 they tried to synchronise their movement with it. RTs and CorTs (for outward movements only) were measured from ultraviolet records to an accuracy of 10 ms.

Table 1 Reaction times for correct movements

Class of movement	Trials	N	Mean (ms)	s.d. (ms)
A Follow irregular pattern	1 and 7	270	211	44
B Follow regular pattern	2 and 6	270	173	70
C Predict regular pattern	3, 4, 5	360	−199	319
D Correct moves to SJs (median for each S)	4, 5, 6	15	214	36

Table 1 lists overall RTs for correct movements in the various conditions. Each estimate is derived from six or eight movements made by each subject in one or two samples taken from the trials listed, except 1*D* where numbers varied between subjects and the median score for each subject was used for the calculation. (1*D* represents RTs for correct movements at SJs.) Within all these classes of movement initial ANOVAs showed that there were no significant differences due to samples, trials or directions of movement. RTs for conditions 1*A* and 1*B* are similar to those found elsewhere[1,10,11]. 1*C* shows that subjects were predicting on trials 3, 4 and 5, since their RTs were mostly negative, and rarely longer than +120 ms.

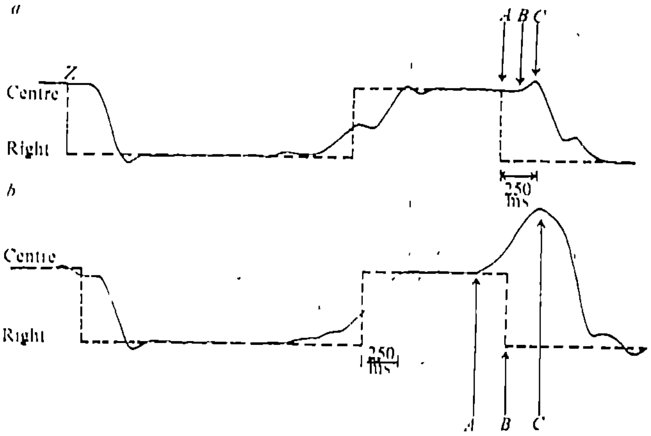

Fig. 1 Record tracing of wrongly-predicted movement. Dotted line, target; continuous line, subject. The track runs from left to right. *a*, At point *Z* the subject makes a normal aimed movement to the right, with an RT somewhat shorter than those to irregular target movements. At *B* he begins a movement to the left (expected direction of target jump) when the target in fact moves to the right again (point *A*). *A*—*B* = RT (140 ms); *B*—*C* = CorT (110 ms); this is much shorter than the average RT to follow the target, so the motor pattern initiated by an order from the voluntary decision mechanism is not completely ballistic once it has begun. It may be shut off during its execution if necessary, but only if it begins some time after the target jumps; the total time RT+CorT is still at least one normal RT. *b*, At *A* the subject commits himself to a movement in what turns out at *B* to be the wrong direction. *A*—*B* = negative 'RT' (−170 ms); *B*—*C* = CorT (230 ms); this is about the same as the subject's normal RT. The CorT *B*—*C* here is about equal to the combined RT and CorT of corrections in *a*. When the subject is committed to his action in advance of the error signal, therefore, CorTs are not shorter than the normal RT, and are often rather longer.

1*D* shows that responses which correctly follow an unexpected direction of movement only do so after a lag of duration similar to the normal RT for irregular jumps 1*A*, that is, when the signal tells the subject which way to go. These RTs are significantly longer than those of 1*B* where the signal tells the subject when to go, the direction already being known ($t = 2.322$, $P < 0.05$ for 15 subjects).

Table 2 lists RTs and CorTs for incorrect predictive movements at SJs. Those begun after the target jumps (Fig. 1*a*) show evidence of relatively fast error correction (180 ms), this being roughly equivalent to RTs for the regular pattern (Table 1*B*), suggesting that a 'stop' order may take only as long as a simple 'go' order. The shortest CorT found in these records was 70 ms, and a dozen or so were less than 100 ms, which is shorter even than the time suggested for a motor system servo to adjust by some internal feedback[13], so there may not be a minimum value of CorT for cutting off a movement in progress. Shorter CorTs than this, however, may be difficult to distinguish from natural tremor, although there was little evidence of the latter in these records—movements started and stopped quite distinctly on most occasions (for example, *Z* in Fig. 1*a*). Very short CorTs only occur, however, where the onset of the action is delayed, and the error signal therefore has time to begin its passage through the central nervous system before the movement starts. When RT and CorT are added together (2*A*, bottom line), correction times again average about 300 ms from the time of the error signal.

Table 2 Reaction times and correction times for errors at SJs

Class of RT/CorT	Trials	*N*	Mean (ms)	s.d. (ms)
A, Incorrect movements with positive RTs: (median for each S)				
—RT	4, 5, and 6	15	143	41
−CorT	4, 5, and 6	15	181	53
−RT+CorT	4, 5, and 6	15	309	52
B, Incorrect movements with negative RTs: (median for each S)				
−RT	4 and 5	15	−231	117
−CorT	4 and 5	15	309	98

Where incorrect movements begin in advance of the target jumping (Fig. 1*b*) subjects need about 310±100 ms to stop an ongoing movement. This is close to the minimum value reported by others for stopping an action[5–7], or adjusting it through vision[14].

These results suggest: (1) fast error-correction can occur from an external (visual) error signal alone (that is when an efference-copy explanation cannot apply); thus (2) movements are not necessarily ballistic in that they may be stopped, if found to be wrong, before they have run their full course. This takes about 180 ms on average, but sometimes only 70 ms or less. It occurs where subjects insert a delay between decision and action which partly bridges the normal RT; but (3) movements cannot be stopped in less than 300 ms from the occurrence of the error signal, that is, visual error correction does conform to the ballistic hypothesis at the highest perceptual-motor 'decision' level; (4) a predictive strategy reduces RT and gives better control where events are redundant, but lays the operator open to predictive error, the duration of which varies inversely with its initial RT. It must last a full RT, if, as in many skills, the action initiated from the prediction runs in time with the events predicted—this is the 'point of no return' of the wartime pilot, batsman or driver in an accident. Subjects working predictively, therefore, trade off a minimum RT for predictable events against the risk of a relatively long CorT for unexpected events when their predictions fail; the payoff values of errors and reactions will presumably determine their strategy in individual cases[1].

This work was supported by the MRC and DHSS. I thank Messrs I. Low and A. P. W. Makepeace for technical help, and Miss P. Heard, Dr J. Harris and Dr R. Williams for discussion.

Lateralised perception of bilateral chimaeric faces by normal subjects

A COMPOSITE 'chimaeric' figure is one constructed by abutting two different half-figures along a vertical join. Following surgical section of the pathways connecting the two cerebral hemispheres (the commissures), patients subjectively experience a compelling perceptual 'completion' in their perception of both halves of such figures when presented at the midline of vision. This perceptual completion evidently occurs independently in each of the two cerebral hemispheres[1]. The critical condition for this phenomenon might be the disconnection between the primary visual cortices of the two hemispheres. Only those portions of these cortical areas are cross-connected which represent a narrow strip of the visual field in the region of the vertical midline[2]. We, therefore, tested normal subjects with chimaeric faces in which no vertical join was visible. Our subjects then experienced perceptual completion, as we had predicted.

There are at least three primary areas in the primate cortex which seem to be involved in the preliminary processes of visual pattern analysis, and which are known to be organised retinotopically[3,4]. These three areas, known as V1, V2 and V3, give rise to commissural fibres which pass through the posterior splenium to corresponding areas in the opposite hemisphere. However, the cross-connected points are limited to the portions in each area which represent a strip of the visual half-field some 2–3° wide bordering the vertical meridian[2–8]. One function which some of these fibres could perform is to assist the brain in its alignment of information deriving from the two visual half-fields[9]:

Table 1 Numbers of choices based on each constituent half-face (join visible)*

	Response condition					
	Pointing (right hand)		Pointing (left hand)		Verbal	
Response based on	LHF†	RHF	LHF	RHF	LHF	RHF
Mean	6.92	6.50	9.67	7.00	6.42	5.83
S.D.	1.68	2.88	1.37	2.59	1.00	1.40

* The tabulated scores are based upon all 12 subjects of group A.
† LHF/RHF = left/right half-face.

Table 2 Numbers of choices based on each constituent half-face (joint hidden)*

	Response condition								
	Pointing (right hand)			Pointing (left hand)			Verbal		
Response based on	LHF	RHF	Neither	LHF	RHF	Neither	LHF	RHF	Neither
Mean	4.50	5.00	2 50	7.00	3.13	1.88	2 57	3.43	1 00
S.D.	1.31	1.31	—	1.51	0.83	—	1.51	1.40	—

* The tabulated scores refer only to those subjects of group B who did not spot the stimulus asymmetry during the relevant test condition. There were eight such subjects in the manual response condition, and seven in the verbal response condition.

this might proceed by a constant process of subtractive cross-matching between similar feature-detecting units with correspondingly-placed receptive fields in the two adjacent half-field strips. The use of some such process could account for observations that an immediate impression of symmetry or asymmetry in a dot-pattern is based, other things being equal, on the symmetry or asymmetry of only the middle region of the array[7].

If this argument is valid, then it might be these splenial fibres which enable the normal observer to detect readily the true nature of a centrally-flashed chimaeric figure. If so, then this detection should become very difficult if the central portion of such a figure were concealed; and since then no mis-match would occur, perceptual completion should be experienced.

We used two groups of 12 subjects, undergraduate students aged between 17 and 25. Both groups were tested comparably, viewing a series of chimaeric faces (made from colour photographs), each back-projected for 100 ms on a translucent screen at luminance levels of 30–40 Ft.L. A total of 24 chimaeric faces mixed with 12 normal faces were given first, the subject in each case being required to identify by pointing the face (or faces) he had seen, from amongst a total set of 12 possible faces. For the first half of these trials, the right hand was used in pointing, and for the second half the left hand. Next, a subset of six faces were given names, which the subject memorised. A second series of colour slides was then presented (seven chimaeric, six normal) with the subject in each case naming the face(s) that he had seen. The left/right occurrence of half-faces was balanced either within subjects (pointing condition) or between subjects (verbal condition). With one group of subjects (group A) conventional chimaeric faces were used, whilst with the other (group B), the same photographic originals had been overlaid with a vertical white strip of paper before the final photographic stage. The mean angular size of the faces (ear-to-ear) was 25°, and of the blank strip 5.3°. In all cases, the projected picture was centred on a spot on the screen which the subject was required to fixate.

The subjects of group A soon realised that they were viewing asymmetrical faces (between two and six chimaeric slides being required). Choices were not clearly biased in favour of the left or right half-face, except in the pointing condition where the left hand was used (Table 1). Analysis of variance of the pointing responses reveals a highly significant main effect of hand used ($F_{1,11} = 26.69$, $P < 0.001$), but this is confounded with a possible order effect. However, the significant interaction of hands × half-fields ($F_{1,11} = 9\ 00$, $P < 0.05$) reflects the fact that this improvement with change of hand was restricted to an increase in correct selections based on the left half of vision.

In group B, seven subjects never noticed that asymmetrical faces were being used, and the other five required between 11 and 29 chimaeric stimuli before recognising any asymmetry. Except beyond such a point, all subjects in group B indicated (manually or verbally) only one face on each trial. Subsequent careful questioning confirmed that they had always subjectively perceived a single complete face. There was a tendency for these 'completing' subjects to name the face which had been exposed to the right half-field rather than that to the left, but this bias was not statistically significant (Table 2). However, analysis of variance on the choices made by pointing, showed a significant main effect of half-fields ($F_{1,7} = 7.43$, $P < 0.05$), in favour of the left. In addition there was also a highly significant interaction of hands × half-fields ($F_{1,7} = 38\ 45$, $P < 0.001$), again reflecting the fact that an asymmetrical distribution of choices appeared only when the left hand was being used for pointing.

Preventing normal subjects from seeing the join in chimaeric faces did not make them behave exactly like commissurotomised subjects Nonetheless, perceptual completion did predominate in this condition, and several subjects even denied having seen any blank strip. Furthermore, completion evidently occurred irrespective of whether the half-face that determined response was in the left or right half-field.

We have also found that a girl with callosal agenesis, who is impaired in midline stereopsis[8] (see ref. 9), showed perfect perceptual completion using conventional chimaeric figures (with the two halves directly abutting)[10]. This observation agrees with our present suggestions, if it can be argued that her brain has compensated, perhaps through the anterior commissure[11], for all of those visual cross-connections normally passing through the corpus callosum, except for those of visual areas V1, V2 and V3.

We thank Professor G. Ettlinger for his comments on previous drafts of this paper.

Dysmyelination in Jimpy mouse due to astroglial hyperplasia?

SKOFF[1] recently suggested a new explanation for the central dysmyelination in Jimpy mice. He suggested that astrocytic processes branch abnormally in these mutants before oligodendroglial proliferation. This branching continues until it surrounds most axons. It is further suggested that by this mechanism oligodendrocytes are prevented from reaching the axons, thus leading to secondary inhibition of oligodendroglial development and myelin formation. This concept, however, seems to be inadequately supported by the quantitative and qualitative data given.

The difference in the ratio of astrocyte cytoplasm to optic nerve tissue between hemizygous controls and Jimpys which were calculated in the planimetric study (ref. 1, Table 1) seems to be much too small to support the proposed thesis. A comparison against animals of a different strain is not valid. Considering the absolute cell counts (ref. 1, Table 2) the calculated surface area of six missing, non astrological cells (72 in hemizygotes, 66 in Jimpys) must be taken into account, if the ratio is to be interpreted as an expression of true astrocytic hyperplasia.

No illustration from the premyelination period showing the astroglial processes surrounding the axons is presented. The vast majority of axons in Fig. 2 ref. 1 are not in contact with astrocytic processes. Figure 3 in ref. 1 is irrelevant for Skoff"s argument because it is obtained from optic nerve at day 23, that is, 15 d after onset of myelination. The cited illustrations (ref. 2, Figs 7 and 8) are also irrelevant for the same reason. The effects which Skoff claims are probably concerned with pathologies following the primary event. The concept that reactive astrocytosis follows central nervous system pathology is well established.

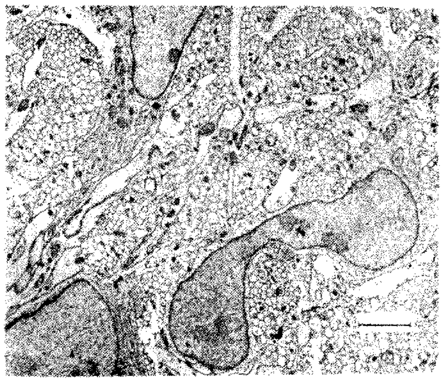

Fig. 1 8-d-old Jimpy mouse optic nerve exhibiting large groups of unmyelinated axons without contact to astroglial processes.

Can astrocytic processes block oligodendrocytes from contacting axons? This hypothesis seems questionable. Blakemore[3-5] produced degeneration of oligodendrocytes, demyelination and heavy astrocytosis in young mice with cuprizone. Demyelinated axons were ensheathed by astrocytic processes. Drug withdrawal led to clear remyelination induced by newly developing oligodendrocytes.

SKOFF REPLIES,—Meier and Bischoff[1] say that the data used to support the hypothesis[2] that astroglial cells may interfere with myelination is inadequate. They claim that the astrocytic processes in Jimpy optic nerve do not contact the majority of the axons before the onset of myelination and that to show this condition afterwards is irrelevant. In the photograph of an 8-d-old Jimpy mouse optic nerve (Fig. 1 ref. 1), Meier and Bischoff state that large groups of axons are not contacted by astrocytic processes. Careful examination of this picture, however, shows that the large astroglial processes send out very fine branches into the fascicles of axons. I have calculated from the original photograph that 77% of the axons are contacted by astrocytic cytoplasm. At this stage, about 2% of the axons in littermates are in the process of being myelinated[3]. In my own 8-d material from Jimpy optic nerve, I have observed that the astrocytic processes not only contact the majority of the axons but they, in part, surround individual axons; this process continues throughout myelinogenesis[2]. I have demonstrated that the abnormal branching of astrocytic processes in the optic nerve begins 2–3 d before the onset of myelin formation. Since this astrogliosis (increase in processes and filaments) begins before myelinogenesis, it is reasonable to conclude that the astrocytic abnormality is not a reaction to abnormal myelination.

In response to the comments[1] that the ratio of astrocytic cytoplasm is too small to support the astroglial hypothesis, these ratios represent a 39% increase over the Swiss strain and an 18% increase over the heterozygote (the term hemizygote was used in the original paper). Concern over the effect of the missing cells on the above ratios is irrelevant since the area of the astrocytic cytoplasm was directly determined rather than by multiplying the number of astrocytes by an average area. The ratios were included to show that the total amount of astrocytic cytoplasm seems to be increased in electron microscopic preparations. It should be stressed that an increase in glial cytoplasm is not essential for an increase in the branching of their processes (two cells of a given volume can take on entirely different geometric configurations).

The Jimpy mice in this study were always compared with their littermates[2]. The Swiss mouse was used as a control for the entire strain because gliogenesis seems somewhat abnormal in most animals of the litter. Electron microscopic observations of Jimpy littermates show varying degrees of astrogliosis in both optic nerve and spinal cord; the number of axons being myelinated in the branchial spinal cord also varies considerably in littermates of identical body weights.

The model of demyelination using cuprizone[4] is important because it shows that normal animals can remyelinate after the drug has been removed from their diets. But this study does not explain the mechanism of remyelination, that is, whether the astroglial cells first withdraw their processes or whether the oligodendroglial cells displace them. In contrast to this model, most human demyelinating diseases[5-8] exhibit an astroglial reaction but the degree or remyelination is poor to nonexistent.

The earliest detectable morphological abnormality in this study of Jimpy mice lies in the astrocytes. To date, there is neither morphological nor biochemical evidence to suggest that the axons are abnormal at the onset of the astrogliosis. It remains to be determined whether the astrogliosis is a reaction of the astrocyte to the axons or if it is inherent to the glial cell. As regards the relationship between the astrogliosis and myelination, the critical question is not so much the cause of the astrocytic abnormality but whether the condition itself interferes with myelination.

Nature of stromatoporoids

KAZMIERCZAK[1] argues that the spherulitic microstructure of stromatoporoids, together with the spherulitic infilling of astrorhizal canals in specimens described from the Upper Devonian of south-eastern Poland, indicate that they have been formed by the calcification of coccoid blue-green algal cells. This suggestion, that stromatoporoids are calcified cyanophyte colonies, is novel and stimulating but it is open to two principal objections. First, it fails to consider alternative explanations of the spherulites; secondly, it overlooks a variety of additional complex morphological features of stromatoporoids.

Stromatoporoids have also been compared with coelenterates[2,3] and sponges[4] and representatives of both groups have skeletons composed of aragonitic spherulites. The similarity of this to the granular or melanospheric microfabric of stromatoporoids has been detailed by Stearn[5]. Several non-skeletal origins of the spherule-like infillings of the astrorhizae described by Kazmierczak[1] are possible, including sedimentation of fine peloidal material, cementation, and recrystallisation. However, Kazmierczak does not deal with any of these points but instead assumes that calcification of coccoid cells must be the origin of skeleton and infilling alike.

The characteristic skeletal features of stromatoporoids such as laminae, pillars and canals together with the not uncommon cyst plates, basal layers and external epithecal coverings, appear to have no parallels in cyanophyte colonies. The permineralised cyanophyte colonies[6] cited by Kazmierczak do not resemble stromatoporoids.

Kazmierczak is essentially proposing that stromatoporoids are skeletal stromatolites[7] of the thrombolitic variety[8]. Stromatoporoids and stromatolites, although superficially similar, differ in external morphology, internal structure, and geological distribution. The complex and varied internal morphology and limited geological range of stromatoporoids, together with their tendency toward discrete forms, strongly suggest that they are higher organisms than cyanophytes.

Do antigen-specific helper factors in rabbit lack V-region Ig determinants?

TAUSSIG, Finch, and Kelus[1] proposed that antigen-specific helper factors derived from T cells in rabbit lack V-region Ig determinants. They further argued that T-cell surface receptor would also lack V-region Ig determinants since the V regions of both the helper factors and T-cell receptor would very likely be the same. Their proposal was based on the finding that sheep red blood cell (SRBC) specific helper factors derived from rabbit carrying an allotypic marker at the a locus in the V region of its immunoglobulins is not adsorbed by anti-allotype antibody (anti-al, Table 2 in ref. 1) conjugated to Sepharose. Since no adsorption occured the authors interpreted it as an indication that the allotypic marker was not present in the SRBC-specific helper factors. In fact, Table 2 in ref. 1 shows that the helper activity is partly adsorbed by anti-al-Sepharose; the number of plaque forming colonies (PFCs) is reduced from 3,200 ± 365 to 2,450 ± 280 as a result of adsorption (Table 2, ref. 1). Since nothing is known about the relationship between PFC and quantity of helper factor used, it is difficult to say anything about the percentage of factor adsorbed by the immunoadsorbent. If the quantity of factor used in the control giving 3,200 ± 365 PFC is far greater than the optimum required (minimum quantity required to give maximum PFC) then the reduction in PFC after passing through the immunoadsorbent observed may be quite significant and represent a substantial reduction in helper activity. But, the authors have not studied the dependence of PFC on quantity of helper factor and not made any attempt to quantitate the factor before and after passing through the immunoadsorbent. It seems to me that the crude data presented do not allow the proposal the authors have made.

If indeed the data show a lack of adsorption of the helper factor by anti-al-Sepharose, then the lack of adsorption can be explained in an alternate way also. Since the helper factor has the capacity to bind antigen and since the factor was generated by incubating lymphocytes with antigen, it is conceivable that the factor is complexed with antigen fragments. These antigen fragments, though non-immunogenic and incapable of sensitising the bone marrow cells, may be large enough to sterically block the allotypic (al) determinant and thus prevent recognition by anti-al antibody. The authors, thus, have not ruled out the possibility that V-region immunoglobulin determinants are present in antigen-specific helper factors and receptor molecules of T helper cells. Whether or not the antigen-recognising sites of T helper cell receptor molecules and the helper factors are controlled by immunoglobulin V genes in rabbit, thus, remains an open question.

G. SUNDHARADAS
Immunobiology Research Center and

University of Wisconsin,
Madison, Wisconsin 53706

[1] Taussig, M. J., Finch, A.P. & Kelus, A. S. *Nature* **264**, 776–778 (1976)

TAUSSIG *et al.* REPLY—Dr Sundharadas has raised certain points concerning removal of the rabbit antigen-specific T-cell factor on immunoadsorbents carrying anti-immunoglobulin (Ig) reagents. The difference in numbers of PFCs which he points out is not significant (at the 5% level). The capacity of the anti-al allotype adsorbent was more than sufficient, on past experience, to have removed the factor had the latter carried the al allotypic marker. As stated in the paper, the method was sensitive to a 50% reduction in factor activity, based on titration. The question is really not whether al-carrying molecules could have escaped detection, but rather whether a proportion of factor molecules greater than 50% could have Ig V regions yet be negative for a allotype, as are about 10% of normal rabbit Ig molecules. This cannot be ruled out, as discussed in our paper. Thus, at the very least our results show that the factor molecules do not carry the Ig allotype in the same proportion as circulating Ig. The further point about possible blocking of the factor binding site and steric hindrance of the allotype we consider unlikely. Evidence against it is that the factor can be absorbed by antigen, indicating the availability of its binding site.

reviews

Basic modern astrophysics

Paul Davies

The Structure of the Universe. By Jayant Narlikar Pp. 264. (Oxford University: London, Oxford and New York, 1977.) £4.25.

THE name of Jayant Narlikar has long been associated with the steady-state theory of the Universe, the absorber theory of radiation and other controversial aspects of modern cosmology. Now he has used his fertile imagination to produce a readable and useful introductory book to astronomy and cosmology. Although the first half of the book deals in a conventional manner with standard topics such as stellar evolution, galactic structure and Friedmann cosmological models, some of the legacies of the author's more speculative past research emerge in later sections. The chapter entitled The Universe and the Arrow of Time will be familiar to those who have read Professor Narlikar's earlier (much more specialist) book written with Sir Fred Hoyle, although the uninitiated will probably be unable to follow the subleties of the arguments about past and future absorbers, and initiates may well disagree with the conclusions.

The text has obviously been prepared with a view to commanding a wide readership which can range from the scientifically-inclined layman seeking an easy-going summary of this popular subject, up to astronomy and physics undergraduates requiring background or introductory reading. To this end the mathematics has been kept to a minimum, and where possible is separated from the main part of the text in special boxes. There is a liberal distribution of graphs and line drawings, some of which seem to have been prepared hurriedly, and one of which (concerning the Friedmann cosmological models) is badly wrong and could be seriously misleading for a student. In spite of these slips, the open style and lucid presentation generally make information retrieval easy and straightforward.

Superficially, *The Structure of the Universe* seems like a popular book. Its jacket begins with the pregnant query "Do black holes really exist?", and follows up with such imponderables as "what is a quasar really like?" In spite of this, black holes only occupy two or three pages buried in the chapter on gravitation, and most of the discussion about this and other much-exposed topics in modern astronomy is explanatory rather than descriptive.

There is an unmistakable philosophical flavour running through the discussion, with the theme that local physics and global structure are somehow interwoven and that recent developments in both observational and theoretical astronomy are beginning to provide a tantalising glimpse of this link. This is an idea certain to appeal to non-specialist readers who are frequently intrigued by the concept of a grand design, but students would do well to temper enthusiasm for this speculation with healthy scepticism, for much of the physics of the 'micro-macro' link such as the absorber theory of radiation and Mach's principle, is not universally accepted. I was a little disapointed that Professor Narlikar, for so long a spirited advocate of the steady-state theory, has not taken the opportunity to present an extended counterattack in its favour.

In summary, this is a nicely written, attractive book, including many useful, if somewhat superficial, discussions of basic modern astrophysics, from an author of international repute. □

Paul Davies is Lecturer in Mathematics at King's College, University of London, UK.

Receptor research

Methods in Receptor Research, Parts 1 and 2. By M. Blecher. Pp. xiv+383 and 385–763. (Marcel Dekker: New York, 1976.) SFrs. 120 per part.

THESE two volumes have been designed to form a laboratory manual giving a more detailed description of methods used in receptor research than is commonly found in papers published in journals. In this aim, the editor and the 41 authors have succeeded. It was decided to omit the receptors for steroid and thyroid hormones because they have little in common with the polypeptide hormones, which take up most of the space. There are three chapters on gonadotropin receptors, three chapters dealing with glucagon receptors, three chapters covering insulin receptors, two chapters on prostaglandin receptors and one chapter each on β-adrenoceptor and on the receptors for acetylchlorine, adrenocorticotropin, oxytocin, vasopressin, thyrotropin, parathormone, prolactin, cholera toxin, lectin and opiates. Each chapter is written by an expert in the field, describing the laboratory techniques in considerable detail. As with other treatises covering rapidly expanding areas of research, it could not be avoided that there are some notable absentees, as for instance the dopamine receptor and α-adrenoceptor.

The editor stresses in his preface that the overlap between several chapters is more apparent than real. The reviewer finds himself in agreement with this view because only too often seemingly contradictory results obtained by different laboratories are due to minor but important differences in the experimental techniques used.

It is not possible to deal with the various chapters, which are all well and clearly presented. The newcomer to the field of receptor research will find the detailed description of many well tried methods useful. In addition, there are two carefully considered discussions of a more general nature: Catt *et al.* deal with problems encountered in the determination of binding constants and of concentration of receptor, whereas De Meyts presents sections dealing with the physico-chemical parameters determining optimal steady-state binding and its quantitative analysis, the factors of importance for the study of the kinetics of hormone-receptor binding, and the cooperative interactions among receptor sites.

These well produced volumes will be essential for laboratories engaged in receptor research. Unfortunately, the high price will prevent their acquisition by many individual workers.

H. W. Kosterlitz

H. W. Kosterlitz is Professor Emeritus of Pharmacology and now Director of the Unit for Research on Addictive Drugs, University of Aberdeen, UK.

Cognitive development

Development of Cognitive Processes. Edited by Vernon Hamilton and Magdalen D. Vernon. Pp. 772. (Academic: London and New York, 1977.) £21.00.

IT was not so long ago that childhood as a distinct state, with its own distinguishing qualities, was not part of the consciousness of our society. Children wore smaller versions of the same clothes as adults, did similar work, and were expected to behave as much like their elders as possible. There were hardly any books either for, or about, children. Judged by the present volume, although the rest of the world has in the meantime discovered childhood in an upsurge of kids' lib., developmental psychology is still in this undeveloped state.

Current psychological models of cognitive processing are based on empirical investigations with adults. In the present book these models seem to have been adopted without questioning their validity for child development. It is therefore not surprising, that most of the conclusions that are reached are of one of two kinds. First, children, from birth or from a very early age, may show certain information handling capacities, which differ little from those of adults. Alternatively, children are much worse than adults on many cognitive operations, though they become better as they get older. This view is expressed in statements such as: "Increasing age brings increasing ability to make cognitive decisions about a task, and to absorb more information"—which is perhaps not too surprising to anyone but developmental psychologists.

Some of the contributors are clearly aware of the shortcomings of this approach. Thus one of the editors urges in her conclusions that investigators should concentrate on the specific qualities and properties of cognitive processes in children. Two introductory, theoretical chapters do not even pretend to a relevance for development, and though in themselves adequate, state nothing which has not been published extensively elsewhere. In spite of the heavy reliance of cognitive models on the analysis of memory functions, which is reflected in these chapters, the book does not even contain an account of the development of memory.

As one might expect from such a miscellaneous collection, quality of style and content varies greatly. The first ranges from barely comprehensible jargon, such as: "It is worth restating, therefore, that human information processing systems may be variably aroused by diverse mechanisms and cognitive events, that they contain dynamically organised goal-seeking programmes, and that they possess an autonomous general capacity and need to continue operations upon inputs and their stores, which elaborate and reorganise their representations long after the event", to the admirable simplicity of statements such as: "We have two eyes and the most natural way to perceive space is through both of them".

There are excellent accounts of perception of form by Vernon, spatial perception by Walk, conceptualisation by Donaldson and language by Cromer. But in spite of the high qualities of these contributions, and notwithstanding the irrelevant, peudoscientific design of the dust jacket, there is little indication in this book that developmental psychology has begun to put forward its own models and theories. These will have to account for the specific qualitative rather than the merely quantitative characteristics of childrens' cognitive processes.

In the meantime, *vivat vivat* Piaget!

Plant embryogenesis

Experimental Embryogenesis in Vascular Plants. By V. Raghavan. Pp. 603. Academic: London and New York, 1977.) £21.00, $45.65.

IN an era of symposia and other multiauthored volumes, V. Raghavan deserves to be congratulated on producing this fine volume dealing with a very complex subject which has an immense literature. The reader is immediately impressed with the breadth of topics and the depth of treatment that most receive.

The first and longest section of the book deals with the development from egg to embryo. Among the topics covered by chapters are: structure and organisation of the egg, zygote and embryo; biochemical embryogenesis; nutritional aspects of embryogenesis—both physiological and morphological considerations; embryo culture; embryogenesis in cultured ovaries, ovules and seeds; nutrition and metabolism of cultured embryos; extracellular control of morphogenesis; biochemical ontogeny of cultured embryos, and applied aspects of embryo culture. I was especially impressed with this section because of the excellent organisation, lucid writing and relating of various approaches to one another. While most of the information deals with angiosperm embryos, references are made to pteridophyte and gymnosperm embryos when appropriate.

The second section discusses adventive embryogenesis, including the induction of both haploid and diploid embryoids. The author has made these chapters very informative, for he has not merely summarised the literature but has tried to make some sense out of the many factors controlling embryoid formation, showing clearly that more work is necessary before these factors are understood satisfactorily. A similar appeal is made in relation to the low percentage of microspores that give rise to haploid embryoids. The last section deals with seed dormancy and germination and no doubt many readers will disagree with the author's decision to include them. The last chapters, however, are useful in giving a full perspective of embryogenesis. The argument is put forth that dormacy involves a mechanism of preventing embryo growth and that factors regulating the normal growth and development of the embryo should also apply to the induction and release of dormancy. All three sections are written with clarity and usefully illustrated with drawings, micrographs and graphs. Unfortunately some of the electron micrographs are printed too darkly but on the whole the book's illustrations are very informative. An appendix containing the mineral salt composition of 18 different nutrient media used in embryo culture should prove useful for many readers. The 103 pages of references should also be valuable to the reader.

In the introduction Professor Raghavan expresses the hope that the book will bring together some of the scattered embryological literature and present the current and future perspectives of plant embryogenesis. The book not only attains that goal in its comprehensive treatment but undoubtedly this book will be the definitive volume on experimental plant embryogenesis for some time. It is highly recommended for all those interested in this most interesting and important area of plant morphogenesis.

William Newcomb

William Newcomb is a research associate at the University of Guelph, Canada.

Magnetic ions in metals

Magnetic Ions in Metals: A Review of their Study by Electron Spin Resonance. By R. H. Taylor. Pp. + 118 (Taylor and Francis: London, 1977.) £6.

THE first observation of electric spin resonance (ESR) was reported by Zavoisky in 1945. Since that time the ESR spectrum of every transition and rare earth ion has been observed in non-metallic solids in one valence state or another. The ESR spectrum is usually studied in single crystals to elucidate interactions between the magnetic ion and its local environment. As a result almost all features of these spectra are understood at least in terms of a phenomenological spin Hamiltonian. There have been many reviews of the properties of magnetic ions in non-metal host lattices: the important results and theory are collected in the encyclopaedic monograph of Abragam and Bleaney (1970). No similar authoritative volume has appeared on magnetic ions in metals largely because the application of ESR to metals developed rather slowly; thus most of the important work has been done since 1970. The history of this development is well compiled by Dr Taylor in this welcome addition to the literature on magnetic resonance.

Reasons for the tardy growth in this particular area are to some extent lost to non-experts on metals, but metallurgical factors including single crystal growth have been especially important. I would hardly agree with the author that the rather dramatic arousal of interest since about 1970 is attributable to "increasing efficiency of spectrometer systems" or to "increase in spectrometer resolution", both experimental factors which have changed little since 1962. This book is conveniently divided into three major parts. After some introductory remarks, Dr Taylor gives a very good summary of the main appliactions of the ESR method to metals: studies of ground state splittings, the ESR bottleneck, exchange interactions of magnetic ions with conduction electrons, magnetic order in concentrated alloys, magnetic ions in type II superconductors are all discussed. But by far the major part of the monograph is concerned with an experimental review of the spectra of magnetic ions in simple metals, binary alloys and intermetallic compounds. It may come as a surprise to some readers how few ions with well characterised spectra have been observed in metal host lattices. Most published work concerns the S-state ions Mn, Fe, Gd and Eu; far less has been achieved with non S-state ions, only Er, Dy, Yb and Ce having been observed at all. The monograph is completed by a most valuable review of possible growth areas for ESR studies of metallic solids.

The major strength of the book is that it says clearly what has been achieved up to 1975. It could have been improved somewhat by a more substantial discussion of both the folklore of the subject (for example, what systems have been tried but found not to work) and the theoretical background. But in all it is a well produced volume which will be a valuable addition to the bookshelf of both workers in the field and physicists more generally interested in magnetic resonance.

B. Henderson

B. Henderson is Professor of Natural and Experimental Philosophy at Trinity College, Dublin, Ireland.

Microbiological aspects of waste treatment

Treatment of Industrial Effluents. Edited by A. G. Gallely, C. F. Forster and D. A. Stafford. Pp. 378 (Hodder and Stoughton: London, Sydney, Auckland and Toronto, 1977.) £7.95.

THIS book combines the work of twenty-two authors in twenty-one chapters covering aspects of waste treatment from general description of the basic processes to the problems and treatment of specific industrial wastes. The depth of treatment varies from chapter to chapter, as might be expected with such a large number of authors. Some topics are dealt with in considerable detail and the authors in these cases quote numerous references; the chapter on Surfactant Biodegradation in Waste Waters is particularly valuable.

The editors should have avoided such obvious mistakes as on page one, where the statement is made that "activated sludge plants began to be operated by 1900 AD", when a later author in chapter 5 gives the correct date for the development of the process in 1914. There is also no reason in chapter five to substitute the term 'trickle filters' for the professionally accepted terms of either 'trickling filters' or 'biological filtration'. In chapter 4 it is difficult to interpret the phrase in the section on the determination of nitrate and nitrite; "clean waste such as potable supplied".

The title of the book would have been more explicit if it had included the word 'microbiological'. The book is heavily biased to the microbiological aspects of waste treatment, and it would have been improved by including better information on the physical and physicochemical aspects of waste treament and an introduction to the modern concepts of mathematical description of the processes.

Despite these criticisms, the book will be particularly useful to postgraduate students working in the field.

The amount of information presented in the book, which includes over 800 references, represents a very useful addition to the British textbooks available. The book is well produced and very readable and, compared to other similar books, is good value at the price.

Agricultural research strategy

Resource Allocation and Productivity in National and International Agricultural Research. Edited by T. M. Arndt, D. G. Dalrymple and V. W. Ruttan. Pp. 617. (University of Minnesota Press : Minneapolis, 1977.) $25.

CAN science be justified in quantitative economic terms? If no convincing reply, one way or the other, has yet been given, some progress has been made towards the economic analysis of one area, namely research carried out to create new agricultural technology. This research is mostly publicly funded and so has identifiable expenditures; moreover, it generates evident benefits, such as increases in crop yields, which can be quantified. It is virtually indisputable that increases in food supply must improve the welfare of mankind.

Griliches's pioneering study of hybrid maize first provided a methodology, and by 1969 it was possible to hold a symposium on *Resource Allocation in Agricultural Research* (ed. W. L. Fishel, University of Minnesota Press, 1971). We now have the Airlie House conference, which takes account of developments since then.

The book consists of 29 papers which were re-written, and edited, after the symposium. This has blunted the sharp edge of controversy, and it might have been interesting to have included one review paper by a devil's advocate. An issue he might have pursued is the gap which exists between theoreticians (especially model builders) and those needing practical techniques.

Even with careful editing, it could hardly be expected that a coherent synthesis of the whole field would emerge, but the papers provide valuable background on several particular aspects. These are: descriptions of agricultural research institutions, especially those for developing countries, economic analysis of national and international agricultural research systems, and methods of planning and organising agricultural research. It may be mentioned that a good account of the conference is available free as a seminar report from the Agricultural Development Council, New York.

Although all the social implications of technical change in agriculture could not be fully explored, the conference has importance as a deliberate attempt at closer collaboration between social and other scientists, an initiative which is to be welcomed.

The main theme was the "social rate of return on agricultural research", a concept deriving from Griliches. It is well known, even notorious, that such calculations lead to very high numbers, but this raises some queries. Why is agricultural research so productive? If so, why do governments not invest more in it? And if subjective planning methods have proved so successful, why seek to replace them by more elaborate, but still untried, methods?

Although a consensus at the conference did not accept it, the suggestion was made that the rate of return is an inappropriate planning indicator, since it implies that there are no constraints on other factors such as land, labour, energy, capital, imports, and so on. Viewed thus, the high rates of return are only artefacts, and the way could then be open for a different and more realistic presentation to governments of the important contribution which agricultural research can make to national economies.

It is possible, therefore, that the Airlie House conference will prove to be a watershed. Griliches's original study has been prolific, but we need to subject the methodology to close scrutiny and to consider developing improved procedures. This could well be the theme for another conference; meanwhile, this volume provides economists and those concerned in agricultural research strategy with a useful source on current thinking.

W. S. Wise

W. S. Wise is Head of the Programmes Section with the Agricultural Research Council, London, UK.

Free-living and parasitic Protozoa

Protozoa. By A. Westphal (in collaboration with H. Muhlpfordt). (Translated from the German by W. H. R. Lumsden and G. A. Targett.) Pp. 325. (Blackie : Glasgow and London, 1976.) £9.90.

WITH a few notable exceptions one rarely finds modern texts which encompass both free-living and parasitic Protozoa. Any new publications in the field are therefore welcomed. This is a book of high technical quality. It is profusely illustrated with delightful line drawings which, combined with a use of clear and varied typeface in the text, produces a book of immediate visual impact.

From the outset the author has imposed well defined limits on the objectives of this book. In the preface he states "it is not intended to be, and cannot be, anything more than an introduction to protozoology". To this end, the book is divided into three sections: the first, which occupies half the text, deals with the taxonomy of the phylum; the second describes the myriad cell organelles found in these organisms; the final section briefly discusses the ecology of the Protozoa.

In the taxonomic section the wealth of illustration excels. Each class is described in the text concisely, although frequently at the expense of clarity. The description is followed by diagrams showing the range of morphology and life cycles in the relevant organisms. This format does however become wearing on the reader when the illustrations are referred to frequently in the text. The inclusion of a systematic key would have increased the practical value of this book.

The description of the cell biology of the Protozoa provides an insight into the amazing complexity of the subcellular morphology achieved in this 'simple' group of organisms. It is unfortunate that the reproduction of the electron micrographs does not match the quality of the line diagrams. Here, as elsewhere in the book, there is a dogmatic tenacity for a scientifically accurate text rather than a simple and readable one. It is inevitable in such a wide ranging introductory book that that author's necessity for generalisation introduces errors in specific instances. Moreover, the description of meiosis and mitosis does not match the standard set by the remainder of the text, and could well have been omitted.

The final chapter of the book, on the Protozoa and their environment, briefly examines the distribution of some common free-living Protozoa and provides a more expansive and highly readable section of the impact of the principle protozoan parasites of man and his domestic animals.

It is inevitable that this not inexpensive book be compared with Grell's *Protozoology*, a book of similar technical layout and scientific interest, which, although much more expensive, covers all aspects in great depth. Although the latter will certainly be the choice of the committed protozoologist, Westphal's text is one that could be considered for many undergraduate applications.

R. E. Sinden

R. E. Sinden is Lecturer in Zoology in the Department of Zoology and Applied Entomology at Imperial College Field Station, Ascot, UK. He is Secretary of the British Section of the Society of Protozoology.

announcements

Appointments

Dr J. H. Steele, to Director of the Woods Hole Oceanographic Institution, October 1977, from his position as Deputy Director of the Marine Laboratory of Agriculture and Fisheries for Scotland.

Dr D. Silverleaf, to Director of Resource Planning, a new post in the Central Electricity Board's recently formed Research Division, from Director of Resource Planning in the South Western Region.

Awards

The French Society of Physics has granted its awards for 1977. The Jean-Ricard Physics Award was received by Roger Balian for his work at the Saclay Centre for Nuclear Studies (Commission for Atomic Energy). Roger Balian is a theoretician of many particle systems and has worked on various subjects from nuclear physics to the physics of condensed matter. He also did research on helium 3 and wave behaviour.

The Jean-Perrin Award for the Popularisation of Science was shared by Robert Clarke and Nicolas Skrotzky from France-Culture.

The Robin Award, generally granted to a physicist for the whole of his work, went to M. P. Cagnac, a specialist in atomic physics teaching at the Paris VI University.

American scientists Seymour Benzer, a biologist, and John Dyson, a physicist, are the 1977 recipients of the Harvey Prize. Seymour Benzer, Professor of Biology at the California Institute of Technology, receives the Harvey Prize in Human Health for his discoveries in molecular and behavioural genetics, and John Dyson, Professor of Physics at the Institute of Advanced Studies, Princeton, receives the Harvey Prize in Science and Technology for his work in the fields of quantum electrodynamics, ferromagnetism, field theory, static mechanics and the stability of matter.

The Institute of Physics, London, and the German Physical Society announce the award of the 1977 Max Born Medal and Prize to Professor W. E. Spear of Dundee University, for his work on charge transport in non-crystalline semiconductors.

The Biochemical Analysis Prize (10,000 DM) donated every two years by Boehringer, Mannheim, BRD, for outstanding work in the field of biochemical instrumentation and analysis. The presentation will take place during the 1978 Analytical Biochemistry conference in Munich from 18 to 21 April. One or several papers concerning one theme, either published or accepted for publication between 1 October 1975 and 30 September 1977, may be sent in triplicate to Professor I. Trautschold, Secretary of the Biochemical Analysis Prize, Medizinische Hochschule Hanover, Karl-Wiechert-Allee 9, 3000 Hannover 61, BRD, by 15 November 1977.

Person to Person

Exchange 3-bedroom house in Mill Valley, Marin County, California, for similar in north Oxford or nearby for one year beginning August/September 1977. Easy commute to San Francisco. Contact David Martin, Jr, Department of Medicine, University of California, San Francisco, California 94143.

Exchange 3-bedroom house easy access Adelaide, Australia, for similar in London area, December 1977 to January 1979. Contact A. Grady, School of Earth Sciences, Flinders University of S.A., Bedford Park, South Australia 5042.

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

Meetings

18–20 July, **1977 Summer Computer Simulation Conference,** Chicago, Illinois (G. Graber, Treasurer 1977 SCSC, Applied Dynamics International Inc., 3800 Stone School Road, Ann Arbor, Michigan 48104, USA).

7–12 August, **1st International Congress for the Study of Child Language,** Tokyo, Japan (F. C. C. Peng, International Christian University, 10-2, 3 Chome, Osawa, Mitaka, Tokyo 181, Japan).

23–24 July, **4th ICU Symposium on Sociolinguistics,** Tokyo, Japan (Department of Linguistics, International Christian University, 10-2, 3 Chome, Osawa, Mitaka, Tokyo 181 Tokyo, Japan).

30–31 July, **2nd International Symposium on Pedolinguistics,** Tokyo, Japan (Department of Linguistics, International Christian University, 10-2, 3 Chome, Osawa, Mitaka, Tokyo 181, Japan).

25–28 August, **The Linderstrom–Lang Conference 1977 on Biochemical Control Mechanisms of Respiration at the Molecular and Tissue Level,** Espoo, Finland (Department of Medical Chemistry, University of Helsinki, Sittavuorenpenger 10, SF-00170 Helsinki 17, Finland).

25–30 August, **International Conference on Chemical Education,** Ljubljana, Yugoslavia (International Union of Pure and Applied Chemistry, University of Ljubljana, Department of Chemistry, RCPU, PO Box 18/1, 61001 Ljubljana, Yugoslavia).

26–30 August, **85th Annual Convention of the American Psychological Association,** San Francisco (Information Office, American Psychological Association, 1200 Seventeenth Street, N.W., Washington, DC 20036, USA).

4–17 September, **Training Course on Membrane Biophysics and Biochemistry,** Cambridge, UK (V. L. Lew, Psysiological Laboratory, Downing Street, Cambridge, UK).

8–9 September, **Conference on The Mechanics of Granular Materials,** London, UK (The Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex, UK).

11–24 September, **Summer School—Thermal Neutron Scattering,** Harwell, UK (B. T. M. Willis, MPD/521.2, AERE Harwell, Didcot, Oxon, UK).

19–21 September, **Biennial Polymer Physics Conference,** Shrivenham, UK (Institute of Physics, 47 Belgrave Square, London SW1, UK).

26–29 September, **1st BOC Priestly Conference on Heterogeneous Oxidation,** Leeds, UK (J. T. Cleave, Special Courses Division, Department of Adult Education and Extramural Studies, University of Leeds, Leeds, UK).

26–29 September, **6th Europhysics Conference on Macromolecular Physics, Phase Transitions in Bulk Polymers,** Varna, Bulgaria (M. Mihailov, Bulgarian Academy of Sciences, Central Laboratory for Polymers, EPS Conference, 1113 Sofia, Bulgaria).

29 September, **Symposium on Food Contamination,** Manchester, UK (G. A. Barker, CPC (United Kingdom) Ltd, Trafford Park, Manchester 17, UK).

Recombinant DNA debate three years on

THREE years this week, the recombinant DNA debate burst into the public spotlight with the publication in *Nature* and *Science* of an appeal for scientists worldwide to defer some types of gene-splicing experiments until their potential public health hazards had been examined. That appeal touched off an extraordinary series of regulatory battles in the United States, and the safety rules governing recombinant DNA experiments have yet to be put into final form. In Europe, meanwhile, most countries have adopted regulatory machinery with very little public interest being expressed in the issues.

In the United States, the matter now rests squarely with the US Congress, with separate bills to regulate recombinant DNA experiments working their way slowly through the Senate and the House of Representatives. The bills have become the focus of a fierce lobbying effort by scientists, and charges of 'Lysenkoism' and political control of basic research are reverberating around Capitol Hill. Though the charges are frequently exaggerated, there is indeed cause for alarm over some aspects of the pending legislation.

The facts are as follows. Last year, the National Institutes of Health (NIH) published a set of guidelines governing recombinant DNA research supported by government funds. The guidelines do not cover research sponsored by industry, however, and they are not backed by inspection or enforcement machinery. Legislation is required to correct those deficiencies, and thus Congress has every reason to be involved in the process. Instead of simply writing the NIH guidelines into legally enforceable regulations, however, Congress is likely to establish complex machinery which could introduce vast amounts of red tape into the support of genetic research. Hence the agitation by scientists.

The agitation is given extra force by the fact that information generated during the past three years indicates that the potential hazards associated with gene-splicing experiments may be more remote than once believed. For example, a special meeting of scientists and health experts, convened by NIH earlier this month, concluded that there is virtually no chance that recombinant DNA experiments could touch off an uncontrollable epidemic. Another good indication of that attitude is the following extract from a lengthy and cogent report on the ecology of *E. coli,* written earlier this year by Dr Roy Curtiss, a respected microbiologist from the University of Alabama who was among the early leaders in calling for strict controls on recombinant DNA research. " I have gradually come to the realisation that the introduction of foreign DNA into EK1 and EK2 host-vectors offers no danger whatsoever to any human being", Curtiss wrote. Thus, while the possibility of hazard seems to be receding, scientists are being faced with increasingly complex regulations.

Most of the complaints have been directed at a bill now before the Senate, written almost entirely by the staff of Senator Edward Kennedy's health subcommittee, but with Kennedy's strong support. The legislation has already been passed by the Senate Committee on Human Resources and is likely to be considered by the full Senate later this month. A separate bill is under consideration by the House Commerce Committee and is expected to be debated by the House of Representatives later this summer.

The two bills differ significantly in their approach. The Kennedy version would establish an eleven-member Presidential Commission to draft new regulations, license facilities and approve individual experiments The House version would require the Secretary of Health, Education and Welfare to draft new regulations, but the regulations would mostly be enforced by local biohazards committees.

The problem with the Kennedy approach is that it would establish a potentially unwieldy bureaucratic arrangement which would require researchers to obtain prior approval for their experiments from a high-level commission. Such arrangements are at present reserved for such matters as the regulation of nuclear power. The House approach offers more flexibility but without any loss of vigilance. In fact, having local committees oversee implementation of regulations is likely to be more effective than vesting such responsibility in the hands of a remote body based in Washington.

So far, the Kennedy bill has been moving through the Senate with alarmingly little discussion. There was no debate at all on the central provisions of the bill at the committee meeting when the legislation was approved, and the only forum for discussion now is the floor of the Senate, which is not the best place for deciding such complex issues. By contrast, the House version was extensively debated by Congressmen during three committee meetings, and it represents a reasonable compromise between political and scientific concerns.

At least the cries of alarm which have been coming from the research community have focused attention on the shortcomings in the Senate bill and there is now some chance that the House approach will ultimately prevail. Nevertheless, the scientists who have been charging 'Lysenkoism' and urging Congress to keep its nose out of basic research should be careful not to damage their case by overstating it. □

A world fit for whales?

Jon Barzdo, Wildlife Consultant to Friends of the Earth in Britain, asks whether the scientific basis for the management of whales through the International Whaling Commission is no more than a facade for the commercial interests of its member countries

WHEN the International Convention for the Regulation of Whaling established the International Whaling Commission (IWC) in 1946 to 'safeguard for future generations the great natural resources represented by the whale stocks' it was naturally heralded as a great advance in the conservation of whales. Indeed it was an advance, as there had been no body controlling the fishery of whales until that time; gray and right whales were given immediate protection, so low were their numbers.

The management system initially used by the IWC classified whales by the blue whale unit (BWu)—a measure of the amount of oil they produced. (1 BWu = 1 blue or 2 fin or 2½ humpback or sei whales.) Thus the system was mathematically rather than biologically based. During its use, blue and humpback whales were fished to commercial extinction. Having reached 6% and 7% of their respective initial populations both species are now protected. In 1963 a Scientific Committee of the IWC recommended the abolition of the BWu. It was abolished nine years later.

Quotas were then set for separate species in different areas, and the maximum sustainable yield (MSY) concept, introduced as the basis for management in 1974 under the 'new management procedure', upheld this system. The principle is to harvest the whales at a level (MSY level) which allows the greatest number of animals to be taken while maintaining a steady population. This is estimated to be about 50% of original population. The intention is to maintain a balance through a higher birth rate and greater availability of food. But this does not allow for competition with other species for krill. Populations of fur and crabeater seal and of penguins both appear to have flourished with the depletion of whale stocks; and we do not know the consequences of man's currently experimental harvesting of krill.

Nor does MSY allow for fluctuations in whale population, or changes in social structure through whale harvesting, or variations in the physical and biological environment (temperature, weather, food supply and so on). Discussing risks associated with different management strategies in the harvesting of baleen whales, J. R. Beddington has shown that as a population approaches MSY level it becomes increasingly unstable, increasingly vulnerable to deleterious perturbation.

Under the 'new management procedure' using MSY, over-harvesting has been such that the IWC has had cause to set zero quotas for fin and Bryde's whales in the southern hemisphere and for fin and sei whales in the north Pacific. For at least five years, and in spite of annual reductions in overall catch quotas, the whalers have consistently failed to reach their quota. Ostensibly as a concession to whaling countries, limits for some species have been regularly set above the previous year's catch level. Not surprisingly, these were never attained. In 1972 the overall quota was 38,600 whales; last year it was set at 27,939. Where do we go from here?

The IWC met in Canberra last month. It made the largest cut in quotas in its 31-year history, a reduction of 10,000 from 1976. The cuts reflect the excessively high quotas of previous years. For minke whales the southern hemisphere reduction of over 300 to 5,690 is a result of the profound lack of data—a problem across the range, and one that increases the difficulty of estimating MSY.

The sperm whale is the most heavily taken species. The world catch limit is 7,356 although it was 23,000 only three years ago, and males have this year been offered complete protection in the north Pacific, though this limit may be revised in November. Britain imports some 8½ million kg of sperm oil (from the creature's head) annually for use in soft fashion leathers and some gear oils. The cost of the oil has been rising fast, not least because the large whales have already been fished out, and the price can reasonably be expected to soar. The leather industry might even start to use some of the range of alternatives that are available.

In 1972 the UN Conference on the Environment in Stockholm called for a 10-year moratorium on commercial whaling. The IWC rejected the call, which is supported by Friends of the Earth (FoE), the International Union for the Conservation of Nature and other conservation bodies. It would allow time for stocks to start recovering, for research into the ecology and populations of whales, and for research into a more efficient and less cruel method of killing whales than that used now.

The moratorium must go on the agenda of next year's IWC meeting. But even if it was approved it is possible that it would not be enforced. For any of the IWC's 16 member nations may legally opt out of any decision of a commission meeting within 90 days; the opting-out procedure is well used and demonstrative of the weak nature of the IWC. In addition, recommendations of its scientific committees have frequently been ignored, notably in 1960 over recommendations regarding blue and humpback whales, in 1962 over quotas and in several years up to 1972 over the use of the BWu. Moreover, there is not a single species whose yield has been sustained under the 'new management procedure'. Most are decidedly diminished.

The International Whaling Commission lacks control and effectiveness and is long overdue for replacement. To rectify this FoE propose the formulation of a UN body to manage the resources of the sea with regard to the complexity of that ecosystem, and for the general good rather than purely that of those with the (albeit ageing) technology to exploit it. ☐

When two academies meet

Peter Pockley in Sydney outlines attempts by Australian science academies to encourage innovation

TWO learned academies in Australia are putting their weight behind a drive to educate the government and the public in the need for a higher level of local innovation in science and technology. The academies involved are the well-established Australian Academy of Science and the fledgling Australian Academy of Technological Sciences. Both have published booklets recently which catalogue and analyse the R&D scene in Australia and which advocate, *implicitly*, increased government initiative in this area of industry*.

Australian industry is frequently attacked for lack of concern for local innovation and for preferring instead to import new ideas. The number of research staff employed in companies with R&D capacity has dropped sharply, by an estimated 40% in the two years 1974–76. Sums invested in R&D by industry itself, though harder to quantify, are believed to have decreased significantly. Dollars from the government for direct support of R&D in industry, through an Industrial R&D Grants scheme for example, have levelled off. And indirect government support, for example through a tax incentive scheme on industry's own investment in R&D, has not been forthcoming.

Although the extent of overseas ownership of Australia industry has been a hot political issue in the 1970s, the accusation that companies controlled from overseas prefer to import their innovations is generalised largely from the vehicle industry; US-owned car companies reported no Australian innovations in 1970–75. UK- and US-owned chemical industry, by contrast, shows a high rate of innovation within Australia. And some of Australia's more dramatic innovations of late have come from government-financed laboratories, notably in CSIRO, which have developed a successful collaboration with local industry. The present Committee of Inquiry into CSIRO is charged with recommending ways and means of facilitating further collaboration.

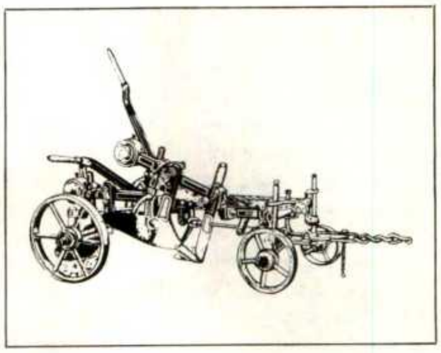
Academy's Forum

The Academy of Science recognised long ago the need for closer liaison with industrialists. Ten years ago it established a Science and Industry Forum with equal membership of academicians (largely basic scientists but including a few with industrial experience) and representatives of industry (businessmen as well as technologists). A pretty informal group holding weekend discussions twice yearly, the Forum has eschewed making recommendations to government but has always managed to attract responsible Ministers and Heads of Departments to its meetings.

Its recently-published set of papers on innovation, under a catchy title and with a commercial distribution and sale system, reflects the Academy's more positive, public face. In the book Sir Alan Walsh, recently knighted for services to science, avers:

> To my mind there are two obstacles to invention and innovation in Australia. The first has its roots in intellectual snobbery which results in many scientists believing that any type of scientific activity which has some real bearing on industry is intellectually and socially inferior to so-called pure research . . . but probably the most serious obstacle is the widspread lack of faith in Australia's ability to generate inventions and innovations which can withstand competition from overseas. In view of Australia's record to date, this attitude is quite ridiculous . . .

The Australian industrialist is more cautious. BHP, Australia's largest locally-owned company, has a good record in Australian-based research and development. Yet its chairman, Sir Ian McLennan, believes there needs to be a "very good reason to commit support to a local invention if the related aims can be satisfactorily met from an available overseas technical development which may be purchased. As there will always be a limit to funds available to develop local innovation these are better spent in a narrower range of likely successes than used over a wide range of relatively ineffectual help . . . " His comments illustrate a growing consciousness in Australia that it is time to formulate and pursue clear national policies on the encouragement of local innovation.



Australia's early innovation: the stump-jump plough

MAAS, Sydney

The Academy of Science is a going force in Australian science, and by far the strongest. With a permanent secretariat, though modestly sized by international standards, it is able to run a range of services to science which goes far wider than keeping happy the exclusive club of its Fellowship of 183 men and two women. The visible presence of its pleasing 'igloo' building on the boundary of the Australian National University has been a significant factor in its influence. Very much a national body, it locks naturally into the bureaucratic, political and academic ethos which dominates the totally non-industrial capital of the nation.

This may have been one of the factors behind a mild blizzard around the Academy's igloo in the 1960s and early 1970s, when a gentle argument about recognition of the applied sciences built up a vortex of discontent. The storm blew around the igloo, only the mildest of breezes being felt within. One of the non-Academician activists was Dr W. A. S. Butement, a former Chief Defence Scientist. He had been leading a move by an informal group dissatisfied with the Academy's terms of admission to Fellowship; these emphasise, as the prime criterion, traditional academic achievement as perceived by peer group elections. The dissenting outsiders tried to persuade the Academy to broaden its terms to include "scientists, engineers and technologists of real worth, who are concerned with the application of science".

Constrained by the terms of its Royal charter, the Academy stuck to its chosen path. Shortly afterwards, however, it did admit to Fellowship some industrially employed scientists. As well as enjoying high standing in the hierarchy of industry, these were men with substantial publications to their name which satisfied the traditional criteria for election of basic scientists. The great majority of technologists employed in industry, universities and government departments were anonymous people by comparison. Thus began a concerted move, centred on an existing, loosely-structured forum of industrial research managers called the Australian Industrial Research Group, for a separate technological academy.

Technological Academy

The Australian Academy of Technological Sciences was formally inaugurated in February 1976 under the Presidency of Sir Ian McLennan.

---

* *From Stump-Jump Plough to Interscan* (Australian Academy of Science, PO Box 216, Civic Square, Canberra, ACT 2608).
Sir Ian McLennan, *Innovation in Australian Technology 1970–1975* (Australian Academy of Technological Sciences, Clunies Ross House, 191 Royal Parade, Parkville, Victoria 3052).

Symbolically, the function occurred in Melbourne, one of the nation's two large industrial and financial capitals; the foundation Fellowship was of 64 men and two women. The earlier rift with the Academy of Science was healed, and cooperation was ensured by the presence of 12 Fellows of the Australian Academy of Science. Criteria for election to Fellowship of the new Academy emphasise innovation, but giving to the achievements of its Fellows a collective, collegiate character is a challenge the Academy has not yet solved.

The "suitable safeguards" surrounding government or industrial documents which involve public reticence on the part of its Fellows put the applied Academy at something of a disadvantage in the public prestige stakes when compared with the freer Academy of Science. The technologists have one potential advantage in coming largely from well-heeled industries which should need little persuading to fork out financial support. But a year-and-a-half after inauguration, the new Academy is still walking along rather than jogging. In its first eight months of operation to mid-1976, it spent a mere $4,000. It now maintains a part-time office in Melbourne, but is run on a spare-time basis by busy men. It badly needs to establish a permanent secretariat to service its present needs and future ambitions.

Australian Information Service, London

AAS's igloo

These ambitions are presently centred on the promotion of innovation in industry and government, and on the mounting of a series of annual conferences on the general theme of "Energy and Resources to 2000". The first of these, scheduled for later this year, is on "Fuel and Energy Resources", followed by "Water and Land Resources" in 1978, "Mineral Resources" in 1979, and "Marine Resources" in 1980. And of course a start has been made in publishing the first results of a review of innovative technological achievement in Australia.

One hundred years ago this year, Australia's first industrially successful innovation was registered—the stump-jump plough. It opened up vast tracts of otherwise useless land to cultivation. This year sees a number of internationally competitive innovations beginning to get public recognition. Successful developments, such as the compact Self-Twist Spinning Machine, the Sirotherm process for desalination by thermally regenerated resins, and the Interscan system for aircraft landing control in three dimensions, may begin to persuade government and industry alike that the two Academies are speaking economic sense when they urge more active support for locally based R&D. ☐

Making paper work

Christine Thomas explains the advantages in using recycled and mechanical pulp papers

FEW people are aware, when they purchase good quality writing paper in preference to rougher note paper, or choose extra-soft toilet tissue rather than lower quality crepe tissue paper, that they are contributing to increasing environmental pollution. But investigation of the demand upon resources and the polluting effects of specific processes involved in paper production highlights the considerable differences in the environmental impact of different papers. The general picture that emerges is that the higher the quality of the paper produced, the greater the resource demand and pollution load created.

Paper consists of a network of fibrillated cellulose fibres bonded together by their gelatinous surfaces. The fibres are released from their plant structure during pulping, which for timber can be either by chemical or mechanical means. Chemical pulping methods use chemical solutions to dissolve away part of the plant structure, leaving the cellulose fibres whole and separated with minimum physical damage. Chemical pulp-based papers are considered for many purposes to be superior in quality to mechanical pulp-based papers. Mechanical pulps are generally weaker than chemical pulps and suffer from colour darkening.

Mechanical pulp papers, however, are of adequate quality for many uses, including newsprint, low grade printing papers, fibreboard, wrapping papers, and some tissues. And mechanical pulping provides a more efficient use of timber with a 90–95% yield of pulp from cut, dried wood compared to 40–65% for chemical pulping. Put another way, where it takes on average 13 trees to produce a tonne of chemical pulp, only six would be needed for mechanical pulp. And it is not only the resource demands of chemical pulp which are greater. Its production also creates a significantly more polluting effluent, and consumes more water than does mechanical pulping (see Table 1).

Waste paper can be recycled by repulping and releasing the cellulose fibres from their existing network to allow them to be reformed into a new sheet. Naturally the substitution of recycled papers for those containing virgin pulp will result in a reduction in demand for wood pulp, and will lessen the problems of solid waste disposal. In addition, however, it will result in a reduction of energy demand, of the order of 50% of the energy required for the wood pulping process. It may also lead to less overall pollution, and a saving in water (see Table 2).

Recycled papers themselves vary considerably. Because the fibres have previously been prepared for papermaking, the recycling process in theory is simpler than pulping wood. In practice, though, there are complications introduced by the presence of ink and

---

Christine Thomas, author of The Paper Chain, *is a researcher at Earth Resources Research Ltd, London* contraries in the waste paper and by fibre damage due to repeated pulping. The highest grades of waste paper will produce high quality recycled papers with little or no upgrading and will create little environmental impact.

Most waste paper potentially available for recycling, however, requires some upgrading, and here the final product's quality becomes particularly relevant to the environmental impact. A bright, relatively high quality paper, made from low grade waste paper and requiring the fibres to be deinked, will consume more energy and water and will create more pollution than a lower quality paper produced from the same waste furnish. Hence, although an increase in recycling will reduce the overall environmental impact of paper manufacture, this reduction will be smaller if present high quality standards are maintained.

Encouraging recycling

How might attitudes towards paper quality be changed to encourage preferential use of recycled and mechanical pulp papers? The paper industry's resistance to using recycled fibres in some products is partly due to the resultant reduction in quality, which they maintain would not be acceptable to consumers. Whether the consumer or the paper industry needs re-educating, the government could take a positive lead by issuing advice and directives on paper quality standards to its stationery office, to local government and to government departments. This would both encourage a change in attitudes to paper quality and stimulate demand for recycled papers, thereby helping the paper industry to use more waste paper in more of its products.

Such a move could not be expected on environmental grounds alone; but there are strong economic reasons for recycling more waste paper. In 1974 Britain consumed 8.7 million tonnes of paper and board products, of which 47% was imported. Of the remaining 4.6 million tonnes produced in Britain, 45% of the furnish was from imported wood pulp. These pulp and paper imports cost Britain over £1,000 million in that year.

The British paper and board industry's heavy reliance on imported wood pulp puts it at a considerable competitive disadvantage to integrated pulp and paper industries abroad, and this has resulted in increasing dependence on imports of finished goods. In 1960, 77% of all paper and board consumed in Britain was home produced, but by 1974 this figure had dropped to 53%. The industry has suffered contraction and decline. Since 1965 over 30 mills have closed and employment in the industry has dropped by about one-third.

In the face of economic necessity the paper industry is slowly increasing its capacity to recycle. There are considerable obstacles facing a significant increase in waste paper use. Acceptance of lower quality is only one. Plant modifications and availability of waste paper supplies are equally, if not more, important problems to overcome. The government, recognising the former problem, allocated last June £23 million for grant aid towards capital investment for increasing the use of indigenous fibres. With only £6.5 million taken up a year later both the effectiveness of the scheme and the industry's commitment to a significant expansion of recycling are open to question.

The dominant problem in discussions of waste paper recycling concerns its collection. Potentially the waste paper is there, as Britain currently recycles only 27% of its total consumption. But instability in the market has severely weakened the collection network.

To overcome this problem, much of the effort has been focused, unsuccessfully, on stabilising the market. The tasks of building up the capacity to recycle and changing attitudes to paper quality are as important. Indeed, the strong interdependence of these three factors means they must be tackled together. □

Table 1 Average fresh water demand and discharge of pollution from pulping and papermaking in Sweden, 1970-71

	Fresh water demand (m^3/m tonne)	BOD_7[1]	Water pollution Colour	Water pollution Solids	Air pollution[2] (kg/m tonne)
Sulphate pulping[3]	250	50	210	30	20
Sulphite pulping[3]	375	90	85	40	50
Mechanical pulping[4]	50	15	—	20	0
Papermaking	130	—	—	50	0

[1] Discharge of organic matter is measured by Biological Oxygen Demand (BOD_7 in kg/tonne product) and colour (platinum units in kg/tonne product). Figures include contributions from accidental discharges.

[2] Sulphur emissions calculated as sulphur dioxide. Sulphur emissions from oil-fired boilers not included.

[3] Bleached softwood.

[4] Unbleached stone groundwood.

Recycling awaited

Presidential pardon

President Carter's pruning of the White House bureaucracy has spared two science-related offices. Colin Norman reports from Washington

PRESIDENT Carter last week took the first and, he said, "for me the most difficult" step in carrying out his oft-repeated promise to slim down and streamline the federal bureaucracy. He announced a major reorganisation of the White House and the Executive Office, including the abolition of seven offices and the eventual elimination of about 250 jobs, a 15% reduction from present staff levels. In spite of early indications that the fledgling Office of Science and Technology Policy (OSTP) and the Council on Environmental Quality (CEQ) would be among the casualties, both have been spared. They will, however, be required to play their part in the weight reduction programme, and they will lose a few responsibilities.

The overall plan is being billed as a move away from the 'Imperial Presidency' and an attempt to strengthen the role of Cabinet members in formulating Administration policy. Declaring himself "very much opposed" to having the White House in total control of government agencies, with reference to the Nixon White House left unstated but clearly implied, Carter underlined the political importance he attaches to the reorganisation by announcing the plan personally at a packed press conference.

In fact, the offices slated for extinction had mostly been grafted on to the White House by Congress, and their elimination will not be too fiercely resisted. They include the Office of Drug Abuse Policy, the Council on International Economic Policy, the Office of Telecommunications Policy, and the Federal Property Council. The real power centres, such as the National Security Council, the Office of Management and Budget and the Council of Economic Advisers have emerged relatively unscathed. It should also be noted that the White House and Executive Office staff has in fact grown during the first five months of the Carter Administration, from 1,655 to 1,712; the proposed reorganisation will slim it down to 1,459.

As for OSTP, it has come out of the reorganisation in a surprisingly strong position. Though the plan would reduce OSTP's staff from the 32 authorised by Congress to 22, the office would also lose some time-consuming functions, such as the preparation of an annual report on the state of science and technology in the United States. Moreover, since OSTP is still getting under way, it had not filled all of its allotted positions; the staff 'cut' will in fact hold the office to about its present size.

Frank Press, President Carter's science adviser and Director of OSTP, told *Nature* last week that he thinks the plan "looks very good", noting that he has retained all of the central functions of the science adviser's office.

The plan would do away with the President's Committee on Science and Technology, a panel established by the legislation which set up OSTP. The committee was supposed to conduct a two-year review of federal support for science and technology, and recommend changes in the government bureaucracy dealing with research and development. Since Carter has a team of his own looking at government reorganisation, the committee's responsibilities will be taken over by that team and OSTP will be consulted. Committee members were in fact appointed late in the Ford Administration but they have never been reappointed by President Carter, and thus the committee had already informally been scrapped.

Two other important science and technology committees will also have their responsibilities changed under the plan. They are the Federal Coordinating Council for Science, Engineering and Technology (FCCSET), which consists of government officials from agencies which have responsibility for R&D, and the Intergovernmental Science, Engineering and Technology Advisory Panel, a committee chaired by the science adviser which is designed to provide a link between federal R&D programmes and state and local officials. FCCSET will become a sub-cabinet working group, chaired by the President's science adviser, and it will retain its responsibility for coordinating federal research efforts which span several agencies. The fate of the intergovernmental panel is still being worked out, but Press said last week

Debating the neutron bomb

AFTER a long and at times bitter debate, the Senate last week voted to approve production funds for the so-called neutron bomb—a small nuclear weapon designed to emit withering amounts of radiation but relatively low levels of heat and blast. The outcome of the debate was assured earlier in the week, when President Carter personally asked Congress to approve the funds. The House has yet to act on the matter, however, and Carter has also said that he will not decide whether to go ahead with production of the weapon until he has given it further study, but last week's vote is regarded as the crucial test.

The vote was 58 to 38, with several Senators who had originally expressed opposition to the weapon voting for it after Carter had made his feelings known. The Senate later approved an amendment, however, that would give Congress 45 days to pass a resolution disapproving production of the weapons if Carter eventually decides to go ahead with them.

Perhaps the most surprising aspect of the debate about the weapons is that it nearly did not take place at all. The bill containing funds for the production of 'enhanced rediation' weapons, as warheads for the Lance short-range missile, was winding its way through Congress and had progressed a long way before the matter came to public attention. Even President Carter admitted during his press conference last week that he didn't know that the funds were in the bill until he read about it in the newspapers.

The weapons are believed to be small fission–fusion devices which would be exploded at relatively high altitudes over enemy troops. The blast area would be limited to a small region immediately beneath the detonation, but neutrons and gamma rays emitted by the explosion would be distributed over a wider area. The idea, as proponents of the bomb have been quick to point out, is that the device would kill people while leaving most of the buildings in the area standing. But it is an extension of past weapons design, rather than a new weapon.

Proponents of the weapon have pointed out that since it would not cause massive property destruction or contaminate large areas with radioactive fallout, it would provide a more useful and credible battlefield weapon than the present, more destructive, nuclear devices. And that is precisely why the weapon has stirred so much opposition—opponents point out that it would lower the nuclear threshold by blurring the distinction between nuclear and conventional warfare. Herbert Scoville, a former top official in the Central Intelligence Agency, wrote in the *New York Times* last week, for example, that "our security depends on strengthening, not breaking, the barrier between nuclear and conventional conflicts".

Colin Norman

that its functions will be retained in some form.

At one stage, it was widely rumoured that the science adviser would be made part of a policy planning unit in the White House and that OSTP would be scrapped as a separate entity. Such a plan was in fact under consideration by the team which planned the reorganisation, but the team changed its mind and recommended that OSTP be retained. "They came to us as disbelievers but walked away believers", one OSTP official remarked last week.

Though the change of mind may have been brought about by the quality of OSTP's contributions to Presidential decision-making (the explanation offered by OSTP officials), an equally important factor is that OSTP has powerful support from the scientific community and from some influential members of Congress. When President Nixon scrapped the former Office of Science Policy, his action was greeted with a cry of alarm from a number of prominent scientists, including a committee of the National Academy of Sciences. A similar outpouring of wrath would have been certain if Carter had tried to eliminate OSTP. He would also have faced resistance from Congress—which would have to approve such a plan—and in particular from Senator Edward Kennedy, who was the chief sponsor of the legislation which established OSTP.

Similar considerations also led to the reprieve of the Council on Environmental Quality (CEQ), an agency in the Executive Office which is required to monitor compliance by other government agencies with the National Environmental Policy Act, and to provide advice to the President on long-term environmental issues. The reorganisation team was seriously considering scrapping CEQ or at least stripping it of some of its major responsibilities, but when those possibilities were leaked early in July, a hue and cry arose from environmentalists. CEQ has long been regarded as a powerful counterweight to federal agencies which conduct large public works or energy programmes likely to affect the environment, and potential demise would have been regarded as a serious blow to the environmental movement, many of whose leaders were quick to remind Carter that they had helped elect him.

In the end, CEQ will be retained, though its staff will be reduced from 40 to 32, and it will continue to monitor environmental impact statements filed by other government agencies.

By preserving CEQ and OSTP, the reorganisation plan has by-passed two potential sources of trouble in Congress, and the plan should be approved without too much of a fight. ☐

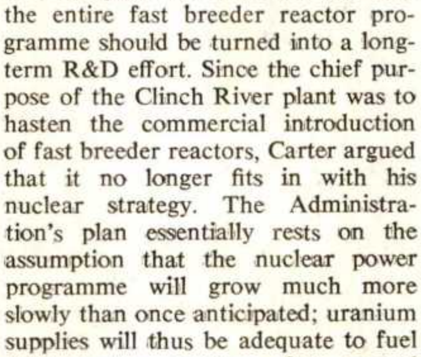
Breeder: far from dead?

PRESIDENT Carter's plans to deter the use of plutonium as a reactor fuel worldwide received a setback last week when the Senate voted to keep the controversial Clinch River Breeder Reactor alive. The move, which came after several hours of intense debate, will not necessarily derail Carter's policy completely, however, for the Senate at least agreed that the project should be deferred for a year, and the House of Representatives has yet to act on the matter. Nevertheless, the vote is being regarded by antinuclear groups as a serious blow.

The Clinch River plant is intended to be a demonstration liquid metal fast breeder reactor, designed to test the commercial feasibility of the fast breeder design. Once expected to cost less than $1,000 million and to be in operation by the late 1970s, its estimated cost has soared to more than $2,000 million and its expected completion date has slipped to at least 1983.

In April, as part of his nuclear nonproliferation policy, Carter proposed that the plant be cancelled and that the entire fast breeder reactor programme should be turned into a long-term R&D effort. Since the chief purpose of the Clinch River plant was to hasten the commercial introduction of fast breeder reactors, Carter argued that it no longer fits in with his nuclear strategy. The Administration's plan essentially rests on the assumption that the nuclear power programme will grow much more slowly than once anticipated; uranium supplies will thus be adequate to fuel light water reactors for several decades, and breeder reactors will not be required to augment fuel supplies by producing plutonium.

The move to downgrade the breeder reactor programme was coupled with another move away from the use of plutonium in the United States. Carter also announced that the United States would defer indefinitely the reprocessing of spent reactor fuel to recover plutonium and recycle it as a reactor fuel. The announcements were designed to bolster the Administration's attempts to dissuade other countries from entering the plutonium economy, the argument being that the United States could not credibly argue against the use of plutonium without renouncing such use itself.



Camera Press

Carter: breeder setback

Although those assumptions were swiftly and sharply challenged by the nuclear industry, until recently it seemed that Carter's plan would be approved by Congress. Fierce lobbying by the nuclear industry and its supporters has, however, produced results.

The first indication that the Clinch River plant may be reprieved came last month when the House Committee on Science and Technology voted to authorise the full $150 million for the project next year, an amount which would allow construction to begin and the plant to be put back on schedule. The House has yet to act on the committee's recommendation, however.

The next move came in the Senate Commitee on Energy and Natural Resources, when supporters of the project, led by Senators Frank Church and Henry Jackson, also proposed that the Clinch River plant should be given $150 million. The committee split 8–8 on the proposal. Church and Jackson then proposed a compromise measure: $75 million should be budgeted for the plant, but construction should be deferred for a year. The rationale, essentially, was that the Carter Administration should use the year's delay to try to persuade other countries not to build their own breeder reactors; if the persuasion failed, the Clinch River project should be given the green light. The committee again split 8–8 on the proposal. Last week, however, after two days of debate, the Senate approved the compromise Church–Jackson proposal by a vote of 49 to 38.

Attention is now being focused on the House, which is expected to take up the mater next week. Though the Science and Technology Committee has proposed giving the Clinch River plant he full $150 million, a compromise proposal along the lines of the Church–Jackson amendment is expected to be offered. Lobbying on both sides is fierce, but at this stage few people are willing to predict the outcome.

EUROPE

Ariane's price

IF evidence is needed that the problems of international cooperation in science are more often political than scientific, the experience of the European Space Agency (ESA) is worth considering. Right now it is in the middle of its latest lurch towards compromise.

The immediate problem is money—about 7.7 million units of account (mua) of it (1 ua=£0.622). That is the amount needed to cover the extra costs imposed by the decision to transfer the launch of the scientific satellite Exosat from a US Thor Delta rocket to ESA's own heavier Ariane launcher.

The decision was reached when ESA's Council met at the end of last month, and is frankly admitted to have been political. The original plan was for a Delta launch, and tenders for the spacecraft were submitted on that basis. But an Ariane launch was always possible, and Ariane is expected to have completed four development flights (three of them with payloads) by 1980-81, when Exosat's mission of measuring cosmic X-ray sources is due to begin.

With so much money invested in Ariane and a flight available anyway, not to use it for Exosat would, it was felt, have reflected a lack of confidence. Recent unfortunate experiences with the Delta rocket, however—most spectacularly with Geos—have apparently had little influence.

When the change came, the decision was not unanimous. Ariane being a French project, France was its strongest supporter. Britain alone voted against, both in the Council and earlier in ESA's Science Programme Committee (SPC).

ESA's science advisory committee, which unlike the SPC and Council is not an executive body with national delegates, also resisted the idea. Its membership of six scientists considered the matter at the end of last year and expressed reservations about both the delay and the risk involved in an Ariane launch.

The worries are straightforward. The scientists want the satellite reliably placed in orbit as soon as possible. Estimates of the likely hold-up vary from three months to a year; it could be longer if Ariane itself goes awry, but if that happens it's probably back to the Delta. One scientist describes any delay at all as "very serious".

Meanwhile, ESA's Council meets again next week, to decide where the extra money will come from. The SPC says it can accept only 4 mua of the total. Britain objects to using funds already allocated for science on a launcher. Delays on Aerosat may ameliorate the problem, but a launch of a second Geos, at a cost of 14 mua, must also be considered. A decision on that is due in September. The options the Council has are not unacceptably limited, and some compromise seems possible. If so, it could be a prelude to something bigger later on if and when ESA's whole programme comes up for discussion.

USSR

Messages from without

Vera Rich describes recent developments involving Soviet dissidents, and speaks to Mark Azbel

FORTY Western nuclear physicists attending the Tenth International Accelerator Conference in Dubna last week sent a message of sympathy to Dr Yurii Orlov, the physicist and dissident who since last February has been held incommunicado in the Lefortovo prison in Moscow in connection with his membership of the unrecognised 'Helsinki monitoring group'.

The scientists' action, on behalf of a colleague whose concern for academic freedom has led him into an active role in the human rights movement, reflects a growing concern with the fate of dissidents like Orlov and a recognition that such protests can be a way of offering genuine help. In the past certain scientists have expressed doubts that this type of action might only exacerbate an already dangerous situation, but since the Twentieth Party Congress in 1956 the Soviet authorities have shown a greater sensitivity to world public opinion, especially when that opinion is voiced by scientists. As Dr Evgenii Levich explained last week at a dinner in Oxford in honour of his father, who was unable to obtain a visa to attend his own 60th birthday conference, "The Soviet authorities are unable to imagine that there is any group of people as important as scientists".

This special status, of course, cuts both ways. According to Professor Mark Azbel, who for the past 2½ years ran the illegal Sunday seminar for refusnik scientists in Moscow, it is particularly difficult for physicists wishing to emigrate to receive visas. "I think that this is related to the fact that the Soviet officials are backward", he says; "they still remember only one thing—that the physicists were the ones who invented the nuclear weapons". For that reason, apparently, mathematicians (excluding applied mathematicians) generally find it easier to get exit visas than others. Not that mathematicians have it easy: Anatolii Shcharanskii, who for some time acted as spokesman of the Seminar and was an active member of the Moscow Helsinki group, is now facing a treason charge.

Azbel was finally allowed to emigrate two weeks ago. He told *Nature*: "I am infinitely happy to become, at last, a free man and a scientist in my native country (Israel). I am infinitely unhappy, however, when I think of all my many friends who are still living in a frightful situation which I know only too well". This, he said, amounted to "gradual scientific death because of the breaking off of scientific contacts, because of lack of laboratories, because of problems with publications, because of absence of conditions for scientific work, to say nothing of the destruction of the health of both the scientists and the members of their families . . . because of the constant persecutions."

Azbel says there are still more than 100 refusnik scientists known personally to him, and that the total number "might be twice as large". This figure, of course, does not include dissidents who do not wish to emigrate. "Western scientists can do a lot," says Azbel, "as the Soviet authorities understand that collaboration with Western scientists is badly needed and that, at the same time, Western scientists do not depend on political fluctuations and that therefore they can hardly be influenced". He himself is certain that it was only due to "all those thousands of people throughout the world—both known and unknown—who supported us in our fight for scientific freedom . . ." that he was finally granted a visa. He urged that each individual case of oppression of a scientist should be taken up by his colleagues.

Ironically, the Soviet Academy of Sciences adopted a resolution last February on the "moral responsibility" of scientists to help their less fortunate colleagues. This was proposed by Corresponding-Academician Veniamin Levich, who, although a refusnik, still keeps his position in the Academy. The resolution was accepted and, as Levich says, is therefore "difficult to ignore", even though it may have no effect on his personal fate. Still, while his birthday conference was taking place in Oxford, Academician A. A. Fedorov, visiting Britain as part of a "peace" delegation, made a statement which suggested that the constant barrage of protests was beginning to take effect in Levich's case. "I hope and believe," he declared, "that Levich will be able to leave the Soviet Union very soon."

- Ernest Akselrod, a psychiatrist formerly with the space programme, who was dismissed on applying for an exit visa to Israel and has since studied psychological and medical problems of refusniks, is to face trial for "parasitism" after refusing to take an alternative job.

USSR

- The Supreme Soviet recently took time out from discussing the new constitution and assenting to Mr Brezhnev's elevation to the Presidency to consider the state of the country's forests. The current Five Year Plan provides for an extensive forestry programme, including reafforestation and planting of some 12 million ha, draining of 1.5 million ha of waterlogged plantations, and routine maintenance of some 230 million ha; the total cost is over 160 million rubles.

The main shortcomings, it appears, lie in the spheres of protection and 'integrated' use of resources. There are frequent cases of wide-spread fires as checks on the observance of fire safety rules and prevention work are not always all they should be. Too little attention is given to the use of scraps and firewood timber which is often left at the felling site. Some timber is lost during rafting and transport or disappears as waste. There is a basic imbalance in the use of timber; the conifer reserves of the Urals and the north are being consumed at an intensified rate, and insufficient use is being made of deciduous varieties.

To remedy deficits in the processing industry, another source of losses, a resolution was passed "On measures to improve further the conservation of forests and the rational use of timber resources". The usual wide campaign of support in the media soon followed. The Deputy Minister of Forests of Byelorussia suggested in an article that new measures may involve a major administrative change; those forests which still belong to collective farms (some 20% in Byelorussia), he said, should not be left "with the former owners", but handed over to the state forestry fund.

- It is only recently that the Soviet Union has acceded to the idea of international control of whale fisheries, and the statement of Vladimir Tveryanovich, chief specialist at the Ministry of Fisheries, marking the close of the whaling season, has something of the enthusiasm of the newly converted. Inverting the customary Soviet pride in overfulfilled norms, Tveryanovich proudly announced that this year the Soviet whaling flotillas had reduced the total number of whales taken; nevertheless, he added, "rational use" of the catch meant that both the variety and the quality of the output of the factory ships had been substantially improved. He also noted that scientific teams—hydrobiologists, biologists and technologists—had sailed with the flotilla; their results, he said, will allow correct estimates of whale-stocks to be made so that the whaling industry can be conducted on a more "rational" basis. There is, as always, no suggestion of a moratorium.

In the case of the dolphin, however, these is a strong Soviet commitment to a total ban on hunting, both in the Black Sea and in the Pacific. According to Aleksei Yablokov, a prominent Soviet biologist, although dolphin hunting is totally forbidden in the Soviet Union, Bulgaria and Romania, the Turks still hunt Black Sea dolphins on a large scale. He quoted "figures from foreign experts" indicating that at least 40,000 dolphins are landed from the Black Sea, and almost as many escape from the hunters only to die of wounds. Several Soviet surveys of the Black Sea dolphin population have been made during the past few years; with the present rate of catch, says Yablokov, the Black Sea dolphin will be virtually extinct by the end of the century. As for the Pacific dolphin, between hunters and pollution it may well become a disappearing species within "a couple of years" unless some action is taken.

Yablokov stressed that dolphins are not a suitable source of raw material for industry. The skins and fat are of low value, and their meat is inedible. This last statement contrasts curiously with the campaign of 1930 which claimed that dolphin meat (in the form of sausages and other delicatessen) could make a significant contribution to the Soviet food supply, and even earn foreign currency as an exotic export. According to Yablokov, the dolphins still have a role to play in the Soviet economy. Experiments are going forward on the training and domestication of Tursiops dolphins, which tolerate life in captivity well and will breed in captivity.

Whether these somewhat exotic plans for the dolphin materialise, Yablokov's other domestication project seems more feasible. This concerns a small school of baleen whales, living near the Shantar Islands. Since the baleen whale has a relatively small range, Yablokov suggests that they might be herded in a similar manner to reindeer, with herdsmen seeking out the best "pastures" for them, and protecting them from their natural predator, the killer whale.

- The discovery of a baby mammoth, preserved in the permafrost, is proving a most exciting challenge to Soviet palaeontologists. It was found by a bulldozer operator cutting peat on the banks of the Kirgili river in the Magadan goldfields. According to Academician N. A. Shilo, the head of a special commission investigating the find, it is the best-preserved specimen so far discovered. Interviewed in *Pravda*, he said the young mammoth was 115 cm long, 104 cm high, and had a trunk length of 57 cm. The body was covered with reddish-brown hair. It was, apparently, some six months old at the time of death.

- A new 'primary standard' based on a special time and frequency system came into force throughout the Soviet Union on 1 July. The latest time standard, designed at the Institute of Radio Physics and Electronics of the Academy of Sciences of the Ukranian SSR, is based on a ruby rod maintained at 2 K which transforms electromagnetic energy into acoustic waves with a frequency of 10^{10} Hz.

At present the Soviet Union has 105 State Standards; by 1980 there should be some 140. According to V. I. Kipichenko, Head of the Metrology Board of Gosstandard (State Standard Committee), the fundamental standard of length—defined in terms of the wavelength of ^{86}Kr radiation—"is not proving fully satisfactory in present-day conditions". An intensive research programme is accordingly under way to produce a standard of length based on laser radiation which, he says, will make it possible to link the standard length to that of time.

The laetrile question

SIR,—There is no lack of "freedom to use harmless drugs", but freedom to promote and sell worthless remedies is constrained. Laetrile (which is not harmless), is the latest and most ingeniously promoted of a long string of such money makers. Croft's first consideration (14 July, page 100) implies that because scientists have been wrong before, therefore they are wrong this time. It is a favourite ploy of laetrile promoters' modesty to compare themselves with the Wright brothers, Louis Pasteur and other shatterers of precedent.

His second consideration, the "resentment of the wealth that medical doctors extract" is an example of the "principle of compensatory evil". Apparently it is alright for doctors to make money by prescribing laetrile. His third point seems to imply that the consumption of a cyanogenic glycoside is part of the pursuit of happiness. Unfortunately, the quest sometimes ends with the use of a stomach pump.

Would Jukes turn people away from Lourdes? Alas, I might if the admission fee were $1,500, coupled with a promise to cure cancer.

Yours faithfully,
THOMAS H. JUKES

Nutrition planning

SIR,—In his attack on the present state of nutrition planning (30 June, page 742), Donald McLaren makes some characteristically trenchant points regarding the nature of the world's food 'problem', but seems to be attacking the wrong target. Surely the failure of the Green Revolution, as failure it probably is, is a classic case of the non-holistic, piecemeal approach which he advocates. It was precisely because (for reasons not unconnected with that inelegant term, agripower) no thought was given to the economic, educational and organisational needs associated with introduction of improved crop varieties, that the increased potential yields of these varieties did not manifest themselves as improved nutrition for the mass of poor consumers.

To implement lasting improvements in nutrition, it is surely necessary to investigate not only biochemistry, but also land tenure, demography, the availability of water and fertilisers, political power-mongering and so on, for the relevant area. Such an analysis is, by definition, holistic. As McLaren himself points out "the widespread problem (. . . .) has socio-economic roots".

I share McLaren's doubts regarding "Utopian social engineering" and "holistic day-dreaming"; similarly the systems engineering approach of the space programme is likely to be totally inappropriate in tackling nutritional problems. Despite this, a broader approach to the study of nutrition, involving economic and institutional factors, even, possibly, the occasional maze of flow diagrams, seems to be essential. This is certainly the approach adopted in our 1978 Open University course, Food Production Systems, of which McLaren's paper on 'The great protein fiasco' (*Lancet* 93–6 1974), forms an integral part.

Yours faithfully,
R. M. MORRIS
Open University, Milton Keynes, UK

Unemployed scientists

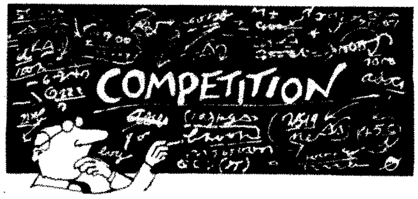
SIR,—I agree with Dr Klein's comments (23 June, page 665) and would like to raise a related issue. The dire problem of post-PhD employment is still to be fully debated in Britain. The number of qualified scientists in their late twenties and early thirties with no permanent job is rising fast, especially in biology. Universities seem to be passing such people over when filling posts recently, and the reasons for this are twofold: young (ie early twenties) post doctoral job applicants are cheaper to employ and, perhaps more insidious, there is a feeling that older candidates may compete for seniority with their longer employed, colleagues of equal age.

In the long term, such practices must be harmful to the academic community. In few other countries can an individual of 23 or 24 years of age, even perhaps five years older, be regarded as intellectually mature enough to acquire a permanent post tenable for the remainder of his working life. Here in Germany for example, the normal procedure is to spend up to six years as an *Assistent* before competing for a permanent university post.

I would like to see a list of senior, non-tenured scientists drawn up for each discipline, and circulated to the relevant university departments. Any PhD would be eligible to join this list at age thirty or so. Before advertising any post, the university concerned should first consider senior scientists on the list, and should offer the job to any suitable candidate thereby found. If none are eligible, then the post could be freely advertised.

By using a system of this kind, the backlog of skilled labour would rapidly be incorporated. Post doctoral research funds would take care of younger people waiting their turn, and an accompanying drastic decrease in PhD student numbers for the next few years would help shorten the queue.

Yours faithfully,
ROBERT RANSOM
Visiting Scientist,
Institut für Biologie II,
Universität Freiburg,
West Germany



Competition 14. £10 for the most stultifying, dreary or meaningless paragraph or two on any theme or non-theme (either published or of your own invention). The second leader of *Nature* **258**, page 465 (11 December, 1975) may serve as an example. Closing date: 26 August.

Competition 13 asked for a technological message to a less advanced civilisation out in space. Jeanne Hopkins, on the staff of the *Astrophysical Journal* in Chicago, was a clear winner with the following:

'Congratulations on inventing the wheel! Yes, we do realise that all the tedious manual labour was performed by your grad students—but the idea was yours, and that's what counts. As you have no doubt informed your Grants Committee, your invention will revolutionise warfare; however, massive Government funding will be required to bring it to its full capability. We suggest that you submit a detailed proposal to your government, outlining possible modifications and improvements, along with a target date for each. For example: "Round wheel, target date 30 years. Toothed wheel, 300 years. White sidewalls, 3,000 years." '

Approaches to effective anti-cancer drugs

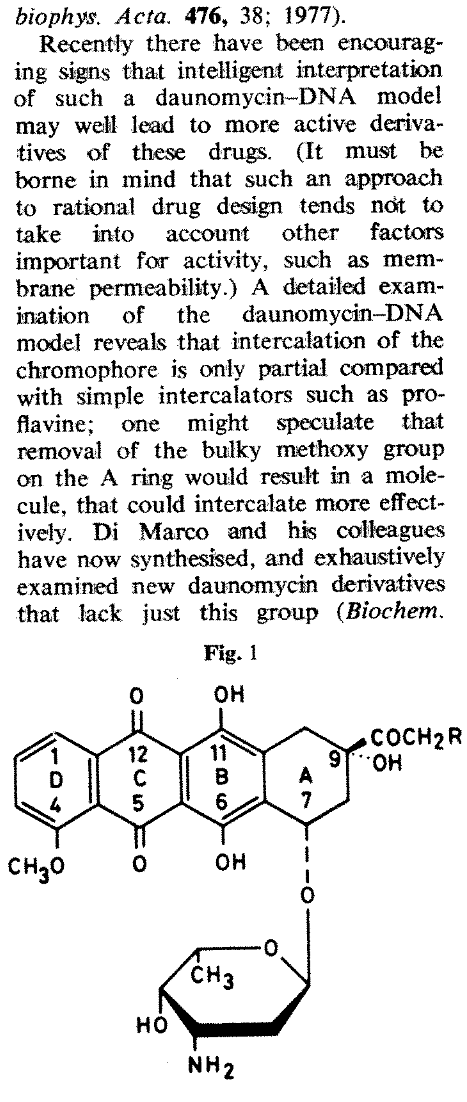
from Stephen Neidle

ONE of the most sobering guiding principles in the development of new drugs is that it is often exceedingly difficult to improve on what nature has already provided. This tenet is especially true in the case of the topical anti-cancer agents daunomycin (R=H) and adriamycin (R=OH) (Fig. 1), first isolated some years ago from cultures of *Streptomyces peucetius* by Di Marco and his associates at the National Cancer Institute, Italy. These two compounds do indeed have considerable clinical usefulness, particularly in the treatment of acute leukaemia; adriamycin has recently achieved promising results with solid tumours as well. However, apart from being cytotoxic, (as are all anti-cancer drugs), they suffer from the very serious drawback of having severe cumulative dose-dependent cardiotoxicity (Lenaz & Page *Cancer Treatment Rev.* **3**, 111; 1976). Much effort has been directed to obtaining either new derivatives, or to developing new dose regimes, that show decreases in undesirable side effects and/or increased anti-cancer activity and selectivity. Such goals are common to many areas of cancer chemotherapy; however, in the case of daunomycin and adriamycin, it is now possible, at least in principle, to take account of recent knowledge concerning their mode of action.

It is now generally accepted that these drugs have as their primary cellular target, nuclear double-stranded DNA, to which they most probably bind by an intercalative process. The consequent inhibition of both DNA and RNA synthesis is more pronounced for cancerous cells, with their higher turnover rate. Some years ago, Pigram, Fuller and Hamilton suggested a generally plausible model for the interaction of daunomycin with DNA, based on X-ray fibre diffraction data and molecular model-building. They suggested that the aromatic chromophore of the drug is intercalated in between adjacent partially unwound base pairs, and the sugar is hydrogen-bonded to the nucleic acid backbone through its amino group. The model satisfactorily explains several features of drug–DNA binding behaviour, perhaps the most striking being a very marked diminution of both binding and biological activity when the sugar stereochemistry is altered, by, say, configurational inversion (Di Marco *et al.* *Cancer Res.* **36**, 1962; 1976; *Biochim. biophys. Acta.* **476**, 38; 1977).

Recently there have been encouraging signs that intelligent interpretation of such a daunomycin–DNA model may well lead to more active derivatives of these drugs. (It must be borne in mind that such an approach to rational drug design tends not to take into account other factors important for activity, such as membrane permeability.) A detailed examination of the daunomycin–DNA model reveals that intercalation of the chromophore is only partial compared with simple intercalators such as proflavine; one might speculate that removal of the bulky methoxy group on the A ring would result in a molecule, that could intercalate more effectively. Di Marco and his colleagues have now synthesised, and exhaustively examined new daunomycin derivatives that lack just this group (*Biochem. biophys. Res. Commun.* **69**, 744; 1976). The modified molecule does indeed bind to DNA somewhat better than its parent. Significantly, *in vivo* testing of these 4-demethoxy derivatives in mouse cancer systems, both of the leukaemic and solid tumour type, show that it is as effective as daunomycin itself, but at dose levels four to eight times lower (Di Marco *et al.* *Cancer Treatment Repts* **60**, 829; 1976).

Fig. 1



The notion of targeting drug molecules specifically to aberrant cells, thus increasing their effectiveness, is a relatively new one. Many types of carrier for the drug can be envisaged ranging from specific antibodies to whole cells. Perhaps the classical example is the DNA–daunomycin complex proposed by Trouet (*Nature new biol.* **239**, 110; 1972) which has, perhaps unsurprisingly, proved to be of questionable value in a clinical context. However, recent reports of the successful use of liposomes (phospholipid vesicles) as versatile general carriers for, amongst others, a DNA–daunomycin complex, suggest that some of the earlier problems, such as susceptibility to endonucleases, can be overcome (Gregoriadis *Nature,* **265**, 407; 1977). Another quite distinct approach has been developed by *Varga et al.* (*Nature*, **267**, 56; 1977). They have capitalised on their earlier findings that the peptide melanotropin binds specifically to surface receptors of mouse melanoma cells; a daunomycin–melanotropin complex was also found to bind strongly to the cells *in vitro,* with a threefold molar increase in toxicity compared with the free drug. Moreover, the complex was not toxic to non-malignant mouse fibroblasts. One awaits with interest the extension of this promising approach to other cell lines, and *in vivo* systems.

The carrier concept in its various manifestations has the potential of, at least in part, overcoming the serious cardiotoxicity of daunomycin and adriamycin. The origins of this property, unique (fortunately!) to these

---

Stephen Neidle is a Cancer Research Campaign scientist at the Department of Biophysics, King's College, London.

drugs remain largely unknown, certainly at the molecular level, in spite of much speculation. A suggestion by Folkers (*Proc. natn. Acad. Sci. U.S.A.* **73,** 4653; 1976) that inhibition of mitochondrial coenzyme enzymes might be an important factor, has been taken up by Lown (*Biochem. biophys. Res. Commun.* **76,** 705; 1977), who suggests modifications to the anthraquinone chromophore of the drugs as a means of surmounting the cardiotoxicity. However, it does seem that such alterations would result in the undesirable effect of markedly decreasing DNA binding ability since the basic requirement for intercalation, a planar chromophore, would no longer be so well obeyed. This illustrates one of the pitfalls of this approach to molecular drug design—how optimisation of one characteristic often results in deleterious effects to others. ☐

Elephants in Uganda

from Robert M. May

For the elephants of Uganda, life has got worse under General Amin. This is supported by the trends recently reported for the number of elephants in Kabalega Falls (formerly Murchison Falls) and in Rwenzori (formerly Queen Elizabeth) National Parks (Eltringham & Malpas *Oryx* **13,** 334; 1976; Eltringham *E. Afr. Wildl. J.* **15'** 19; 1977 and personal communication). The figures in the table are average numbers of elephants for wet seasons only, and are based on aerial sample counts (Eltringham *E. Afr. Wildl. J.* **10,** 299; 1972). The asterisks on the numbers for 1976 denote that they are uncorrected total counts, and therefore overestimates.

These and other African Parks were created at a time when the amount of habitat available to large animals was severely decreasing due to increases in the human population. Until the late 1920s, elephants ranged over 70% of the land area of Uganda; by 1960 the figure was 17%. As a result, large animals have tended to crowd into game reserves and National Parks, often at densities above the carrying capacity of the environment. The problem is particularly acute for elephants, whose feeding habits of uprooting and debarking trees can be very destructive. By the mid-1960s, conditions in the Murchison Falls National Park had so deteriorated that it was feared the Park would erode into a near desert, and 2,000 elephants were shot in an attempt to alleviate matters (Laws, Parker & Johnstone *E. Afr. Wildl. J.* **8,** 163; 1970). The problem of environmental degradation wrought by elephants has arisen in other East African National Parks, most notably Tsavo, and opinion is divided both about the ultimate cause and about the cure (Caughley & Goddard *E. Afr. Wildl. J.* **13,** 39; 1975; Laws *Oikos* **21,** 1; 1970). Neither the optimal density nor the optimal age structure are well understood.

Into this vexed situation, the numbers tabulated above introduce a grim note. The precipitous decline that in 3 years has reduced the elephant population in Rwenzori by a factor of four, and in Kabalega Falls by a factor of ten, is clearly due to poaching for ivory. No attempts have been made to use the carcasses for food, nor to remove the valuable skin from the ears (an elephant hide attache case sells for $600 to those crass enough to carry one). The elephant populations have not even enjoyed the benefits of a thinning, but rather the distribution has changed, with the animals now concentrated into relatively few pockets, where, presumably, they are safest. Eltringham and Malpas observe, moreover, that "the indiscriminate slaughter has caused a breakdown in the normally well ordered family structure: indications of a collapse in the social order are to be seen in the clumping of family units into large amorphous herds. Normally, the family is led by the matriarch which, being the oldest in the group, has large tusks and is, therefore, the poacher's prime target. With the loss of the matriarchs, the leaderless elephants have tended to congregate together, so that locally their density remains high and damage to the vegetation continues."

The experience of the past 20 years has shown that, even with the best will in the world, there are formidable ecological problems in the management of wildlife preserves. For the East African National Parks, the income generated by tourism has provided a practical motive for grappling with these management problems; with the decay of Uganda's tourist industry, it seems that mere anarchy is loosed upon the elephants.

Time	Kabalega Falls (Southern sector)	Rwenzori
Average of earlier counts	8,042	2,633
September, 1973	10,187	2,864
September, 1974	4,072	1,868
September, 1975	1,061	931
September, 1976	1,346*	704*

Binding the *lac* repressor

from Alan D. B. Malcolm

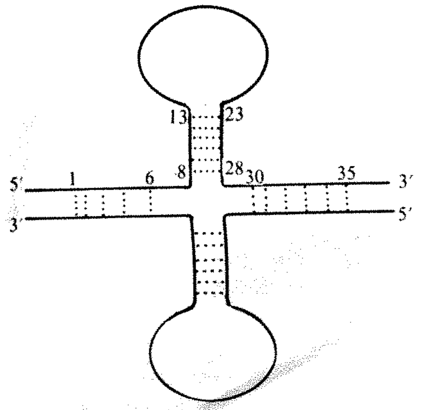
The *lac* repressor protein binding to *lac* operator DNA is the classic example of specific protein–DNA binding, and as such is the best characterised in terms of molecular structure. But it is still not clear why the repressor binds that particular DNA sequence so tightly and how interaction of the repressor protein with inducers such as isopropyl thiogalactoside (IPTG) completely abolishes its capacity to bind operator.

The repressor consists of four identical subunits whose primary sequence is known and studies of repressor mutants have shown that it is the N terminus which is involved in operator binding. Recently (*J. biol. Chem.* **251,** 3386; 1976) Files and Weber showed that trypsin treatment of the repressor removes the N terminal 59 amino acids from each chain leaving a tetrameric core which still binds inducer but does not bind DNA. Geisler and Weber (*Biochemistry* **16,** 938; 1977) have now found conditions for the tryptic digestion so that the intact 1–59 peptide may be isolated (albeit in a mixture with the 1–51 peptide as well). The 1–59 peptide has considerable secondary structure and can bind DNA. However it does so only weakly—with about the same dissociation constant with which the intact repressor binds non-operator DNA. This binding is still thought to be biologically significant however, because kinetic studies suggest that the repressor first binds to any (non-operator) sequence and then moves along the double helix until it locates the operator where it then binds 10^8 times more tightly.

The original operator region sequenced by Gilbert and Maxam consisted of the 27 nucleotides protected by the repressor from enzyme digestion. When the sequence was subsequently extended to 35 base pairs it was clear that there were four regions related by

---

Alan D. B. Malcolm is in the Department of Biochemistry at St Mary's Hospital Medical School, London.



a twofold axis of symmetry—base pairs 1–6 are rotationally related to base pairs 30–35, and 8–13 and 23–28 are similarly related. This of course allows the possibility that the double helix be looped out to form cruciform structures as suggested over ten years ago by Gierer. Jones and Olson (*J. theor. Biol.* **64,** 323; 1977) have now suggested that if the N terminus of the protein is folded into a π helix (which has five amino acid residues per turn), one side of the helix will have tyrosines 7, 12 and 17 sandwiched between Lys 2 and Arg 22 (model studies in many laboratories have shown that such peptides interact strongly with nucleic acids) whereas the opposite face is fairly hydrophobic and would be ideal for facing in to the core of the repressor. If the operator sequence has one looped out section as shown then Jones and Olson are able to propose a perfect fit between the four subunits of the repressor and the four hydrogen bonded regions of the operator.

Unfortuntely this attractive hypothesis has to face several ugly facts. The first is that a search for single-stranded regions in the operator using specific nucleases has failed to reveal any (Marians & Wu *Nature* **260,** 360; 1976). Such looped-out sequences are also out of favour in the λ operator where an expected effect on superhelical density has not been observed. Even more significantly Narang and his coworkers have been synthesising various sections of the operator and testing them for repressor binding. They showed last year (*Proc. natn. Acad. Sci. U.S.A.* **73,** 91; 1976) that the 21-nucleotide long fragment from position 8 to 28 inclusive retains full binding activity although it does not contain either of the outer palindromic sequences. Even more surprisingly, they have now shown (*Proc. natn. Acad. Sci. U.S.A.* **74,** 966; 1977) that the 17-nucleotide long region from 10 to 26 still binds although two base pairs from each of the inner palindromic sequences are now also absent. It is something of a relief to find that anything smaller than this heptadecanucleotide does lose repressor binding ability. It may be that many of the palindromic sequences so far found at operator and promoter sites in prokaryotes are not significant after all, especially in view of the finding (Valenzuela *et al. Nature* **267,** 641; 1977; Maxam *et al. Nature,* 643; 1977) that the 5S RNA promoter in yeast has no palindromic regions at all.

Chemical syntheses of the operator region in which 5-bromouridine or deoxyuridine have been substituted for thymidine have been reported (Yansura *et al. Nucleic Acids Res.* **4,** 723; 1977) and all the various 'mutants' tested bind repressor as well as does the wild type. It looks as though the *lac* operator is going to stretch the abilities of synthetic chemists and biophysicists to the limit before it yields the secret of its repressor binding. ☐

Nitrate in drinking water: health hazard unlikely

from Alan Wild

NITRATE has variously been blamed for algal blooms in lakes and rivers, for methaemoglobinaemia in young babies and most recently as a possible cause of gastric cancer. Fears have been expressed that increased use of nitrogen fertilisers on arable land will lead to a higher nitrate concentration in the water supply, and the Royal Commission on Environmental Pollution in the UK is at present considering the impact of agricultural practices on nitrate concentration in the water supply.

In the UK the Water Authorities follow the WHO standards laid down in 1970 which, for drinking water quality in general, are regarded as 'over-safe' for the UK (Pittwell *J. Institution of Water Engineers and Scientists* **31,** 214, 1977). The WHO recommended concentration of NO_3–N per litre is less than 11.3 mg, 11.3–22.6 mg l^{-1} is "acceptable" and more than 22.6 mg l^{-1} is unacceptable. These standards are based on work in 1945 in which well water contaminated with coliforms (indicators of faecal pollution, another source of high nitrate levels) containing 90 and 140 mg l^{-1} of NO_3–N was implicated in an illness of two infants which was diagnosed as methaemoglobinaemia (Comly *J. Am. med. Assoc.* **129,** 112; 1945). Comly recommended that well water used for infant feeding should possess a NO_3–N content no higher than 10 or at most 20 mg l^{-1}. In the US and several other countries threshold standards of 10 and 20 mg l^{-1} are used. It may be noted that the WHO standards are derived from 50 and 100 mg NO_3 l^{-1}, and 11.3 and 22.6 may imply an accuracy that was not intended.

More recently the fear that nitrate may be implicated in gastric cancer arose from speculations that amines and nitrite react in the body to form carcinogenic nitrosamines, and that the nitrite is formed by reduction of nitrate. There is only circumstantial evidence for this mode of formation of carcinogens (see Mirvish *Specialised Conference on Nitrogen as a Water Pollutant,* Copenhagen; 1975; Doll *Nature* **265,** 589; 1977), and it must be considered yet unproven. It should be noted that with methaemoglobinaemia and nitrosamine formation the nitrate (and nitrite) may come from food or water.

As a society we have to balance the health risk of nitrate in water (and food) against the cost of any requirement to reduce the concentration. The risk is extremely small: only one death in the United Kingdom was attributed to nitrate in water in the period 1950–75, and this followed the use of well water polluted with coliforms (Tayler *Water Treatment and Examination* **24,** 194; 1975). No cases were reported during the drought of 1976 (*House of Commons Parliamentary Debates* 22 February, 1977).

Nitrate concentrations do not often exceed 10 mg l^{-1} in public water supplies, but if they rise above the recommended standard of 11.3 mg l^{-1} the Health Authorities are automatically notified and may issue warnings to parents of young infants to use bottled water.

Concentration in river water in UK

Concentrations in river water become highest during the winter months; this is attributed to drainage from agricultural land (Slack *J. Institution of Water Engineers and Scientists* **31,** 43; 1977), and Water Authorities may then need to blend waters or withdraw some sources from use. Although analyses for 1976 have not been reported in full, it appears that there was an unusually large rise in concentration after the dry summer; for example in the two rivers Avon (Bristol) and Stour, concentrations rose to more than 11.3 mg l^{-1} in October 1976 and were over 22.6 mg l^{-1} for a short period

---

Alan Wild is in the Department of Soil Science at the University of Reading.

(Toms *Seminar Institution of Water Engineers and Scientists* 29 March, 1977).

It is obviously important to know what nitrate concentrations in rivers and aquifers we can expect in the future. Extrapolating from a survey of nitrate in 18 rivers in England and Wales during 1953–67 (Tomlinson *Water Treatment Examination* **19,** 277; 1970) gradual increases can be expected in some rivers but not in others. This is borne out by an increase in the annual average from 7.1–8.8 mg l^{-1} in the river Trent and a small drop in the Severn from 3.8–3.7 mg l^{-1} between 1971/73 and 1975/76 (data abstracted from *Water Quality* 1975/76, Severn Trent Water Authority). The response of aquifers to nitrate input occurs more slowly, but concentrations as high as 40 mg l^{-1} have been found in the unsaturated zone above the Chalk aquifer in Hampshire (Young *et al. Water Research Centre Tech. Rpt* TR 31; 1976). In accordance with results from elsewhere, concentrations were related to ploughing of old grassland and to fertiliser use, especially the former. From the known dates of these events it was calculated that the groundwater moves through the unsaturated zone at a rate of about 1 m per year, in agreement with estimates for tritium migration, and thus higher concentrations of nitrate may reach the aquifer in 20 to 30 years' time. It is not yet known whether, before reaching the aquifer, concentrations will fall to safe levels by denitrification or by mixing with low-nitrate water.

Relative contribution from various sources

There seems to be no estimate for the United Kingdom of the relative contribution of urban, industrial and agricultural sources to nitrate in river water but an estimate from the Netherlands is that 40% of the nitrate entering watercourses is from urban sewage effluents (Cooke *MAFF Tech. Bull.* No. 32, 5; HMSO, London, 1976). Again in the Netherlands, it has been estimated that of the total 32 kg $\mathrm{NO_3}$–N ha^{-1} entering the watercourses from agricultural land, 20% comes from fertilisers, 15% from organic manures and 65% by mineralisation of soil organic matter (Cooke *MAFF Tech. Bull.* No. 32, 5; 1976). There is thus evidence here, and from the work of Young *et al.* that ploughing of old grassland is a major agricultural source of nitrate. In the UK the area (million hectares) under permanent grass decreased from an average of 7.6 in the 1930s to 4.9 in 1946, increased to 5.5 in 1955–57 and declined gradually to 4.9 in 1973 (*Agricultural Statistics for the United Kingdom,* HMSO, London), indicating that the practice of ploughing old grassland has become uncommon. Unfortunately there is little information on the loss of nitrate from sown grassland which is a few years old, or from improved hill grazing land.

Under well manured arable crops the loss from soil and fertiliser nitrogen has been shown to give concentrations of nitrate in the land drains averaging 10 to 18 mg l^{-1} at Rothamsted, Woburn, Saxmundham and Broom's Barn Experimental Stations (Williams *MAFF Tech. Bull.* No. 32, 174, 1976) with higher concentrations in the autumn and after a wet spring. Under heavily manured grassland the concentration in the drainage water is usually less than 10 mg l^{-1} (Hood *MAFF Tech. Bull.* No. 32 201; 1976) and in drainage from unfertilised grassland the nitrate concentration is often less than in the rainfall (about 1 mg l^{-1}) (Cooke *MAFF Tech. Bull.* No. 32, 5; 1976). The most serious problem is therefore under arable crops, which occupy about half the farmland in England and Wales. It was estimated in 1973 that cereals, accounting for three quarters of the arable area received about 10% less nitrogen than that recommended for optimum yields (Church *MAFF Tech. Bull.* No. 32, 92; 1976). A fair conclusion seems to be that the output of nitrate into surface and ground waters from agricultural sources will increase only a little in the future although there will be differences between crop seasons determined by the weather. Nevertheless, when taken together with increased output of nitrate from sewage treatment to reduce the biological oxygen demand of the effluent, and recycling to meet an increased demand for water, the trend of nitrate concentrations seems likely to be upwards, exceeding 11.3 mg l^{-1} more commonly in the future.

The threshold limits set for safe concentrations of nitrate in drinking water are now seen to be critical. There is no evidence to support the WHO limits and we should recognise the absence of risk to adults with concentrations of 22.6 mg l^{-1}, a requirement that Water Authorities can easily meet. With young infants it seems advisable to keep to an upper limit of 11.3 mg l^{-1} until evidence indicates otherwise, and to supply low-nitrate water in bottles as required. An 'oversafe' limit will increase the costs of purifying drinking water and of sewage treatment quite unnecessarily, and might bring unreasonable pressure on farmers to restrict the use of fertilisers (which now produce food worth about £1,000 million per annum). At the same time there is a clear requirement to establish from sound medical evidence the upper permissible limit especially for young infants and to improve the models used for forecasting changes in nitrate concentrations, which means identifying sources and measuring rates of denitrification in surface and ground waters. It is to be hoped that the Royal Commission on Environmental Pollution will allay the unjustified public anxiety over nitrate in drinking water and also point to ways of meeting these two requirements. ☐

Insulin genes into *E. coli:* first step from fantasy to fact

from Peter W. J. Rigby

ONE of the major benefits to accrue to society as a whole from the exploitation of *in vitro* DNA recombination may well be the production by industrial fermentation of medically important proteins such as antibodies and hormones, which are expensive to isolate from animal sources. The most popular scenario of this type involves the production of polypeptide hormones, particularly insulin, by isolating the relevant gene as a recombinant plasmid and forcing the expression of the inserted eukaryotic DNA within *E. coli.* A recent paper (Ullrich *et al. Science* **196,** 1313; 1977) describes the first step towards this objective, the isolation of part of the DNA sequence coding for rat insulin.

This work, performed in the laboratories of William Rutter and Howard Goodman at the University of California Medical School in San Francisco, depends on the already classical approach of copying mRNA into double-stranded cDNA using reverse transcriptase and then inserting the cDNA copy into a bacterial plasmid vector. So far most work of this type has involved genes such as globin, whose mRNA can be obtained in highly purified form (Efstratiadis *et al. Cell* **7,** 279; 1976). After introducing the recombinant plasmids into *E. coli* by transformation, bacterial colonies containing the desired sequence can be identified by hybridisation with an appropriate probe, generally the purified mRNA. Pure insulin mRNA is not available however, and so an indirect approach has had to be adopted. The success of this work has also depended on several ingenious technical developments which should find widespread application in recombinant DNA research.

The first problem is simply the isolation of insulin mRNA, synthesised

Peter W. J. Rigby is a Lecturer in Biochemistry at Imperial College, London.

only in the islets of Langerhans in the pancreas, which is a very rich source of RNase. To circumvent this problem Ullrich *et al.* used a previously described procedure to isolate islets, thus increasing the proportion of insulin-synthesising cells, and then isolated RNA by a method, developed in Rutter's laboratory, for preparing intact mRNA from sources rich in RNase.

cDNA prepared from total polyadenylated mRNA isolated in this way was characterised by gel electrophoresis both before and after digestion with the restriction endonuclease *Hae*III. Undigested cDNA showed a prominent band about 450 nucleotides in length, while the *Hae*III digest showed bands of 180 and 80 nucleotides. The strategy of the subsequent work is completely predicated on the assumption that these prominent bands are derived from insulin cDNA, which should be a major component of the total cDNA.

Double-stranded cDNA synthesised in this way is in fact a single DNA strand with a hairpin-loop structure. In the conventional strategy for cloning such cDNA the next step would be to open the loop by digestion with S1 nuclease, add homopolymeric tails and then join the tailed cDNA to a vector carrying complementary homopolymer tails. A major disadvantage of this approach is the absence of a reliable method to excise the complete insert from the recombinant plasmid. Ullrich *et al.* have overcome this problem by using chemically synthesised restriction endonuclease recognition sites as linkers. The cDNA was digested with S1 nuclease to open the loop and render it perfectly double-stranded; this blunt-ended DNA molecule was then joined at both ends to a decanucleotide containing the *Hin*dIII recognition sequence. Such blunt-ended joining can be performed using the DNA ligase induced by phage T4, rather than the *E. coli* enzyme which requires cohesive termini. The *Hae*III endonuclease fragments were similarly joined to the linker; in this case S1 digestion was unnecessary as *Hae*III produces blunt ends. Digestion of the products of these reactions with *Hin*dIII endonuclease produces DNA segments with cohesive ends, which can be joined to *Hin*dIII digested vector DNA, in this case the plasmid pMB9.

While such cohesive end joining is convenient and simple, it suffers from a major disadvantage in that the vector can recircularise and thus many of the bacterial colonies selected for expression of the marker function carried by the vector are found to contain merely the reconstituted vector, with no insert of foreign DNA. By treating the *Hin*dIII digested pMB9 DNA with alkaline phosphate to remove 5′-phosphate groups Ullrich *et al.*, prevented this recircularisation. Only those plasmid molecules which have annealed to foreign DNA carrying 5′-phosphates can be convalently closed by DNA ligase and thus the background in the transformation step is drastically reduced.

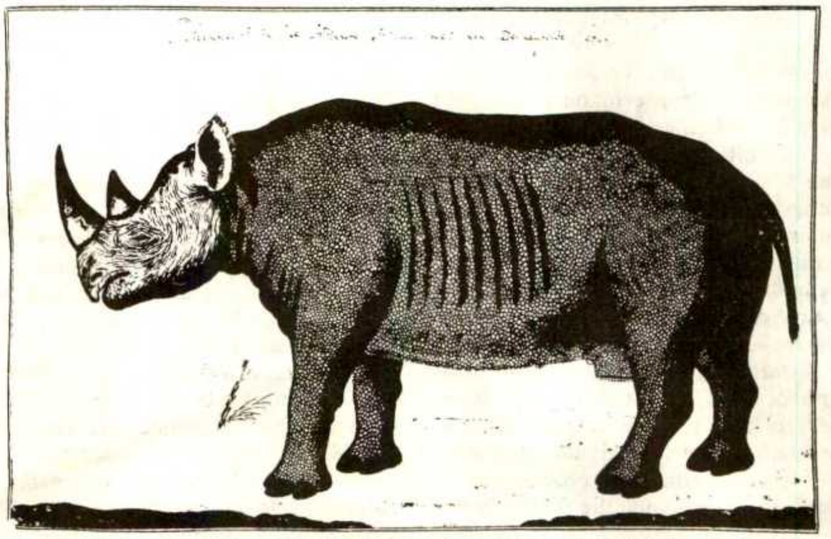


PLATE II. Gordon's second *Diceros bicornis* figure, the head more naturally poised. (Gordon Atlas, fig. 206, Rijksmuseum, Amsterdam).

Illustration from 'Robert Jacob Gordon's original account of the African Black Rhinoceros' (Cave & Rookmaaker *J. Zool., Lond.* **182,** 137; 1977). This provides an account of the memoranda and drawings comprising a description of the African Black Rhinoceros prepared at the Cape of Good Hope in 1778 by Robert Gordon and now incorporated in the Gordon Atlas preserved in the Rijksmuseum, Amsterdam. Although 'Gordon's rhinoceros' was temporarily recognised, Gordon's material never attained independent publication and the historical and anatomical merit of this pioneer investigation went largely unrecognised.

Having introduced these recombinants into *E. coli* by transformation and selecting for tetracycline resistance, the marker function carried by pMB9, the next step in the experiment would normally be to screen for the desired sequence by hybridisation. As no suitable probe was available, crude DNA preparations were made from each clone and these were screened by restriction endonuclease digestion, to look for plasmids containing inserts of 450, 180 or 80 nucleotides, the sizes predicted from the characterisation of the cDNA. One clone derived from total cDNA and containing an insert of 410 nucleotides was identified in this way. By a slight variation on this procedure clones containing the 180 and 80 nucleotide *Hae*III fragments were also obtained.

Even at this stage of the experiment there was no direct evidence that the inserts corresponded to insulin-coding sequences.

The identity of the cloned cDNA was, however, established in the most convincing way possible by direct sequence analysis which showed that it coded for the known amino acid sequence of rat insulin. The immediate product of the translation of insulin mRNA is preproinsulin, which is processed to the mature hormone by a series of proteolytic cleavages. The four plasmids isolated together cover the whole of the proinsulin coding sequence as well as part of the N-terminal pre-peptide. Unfortunately none of the clones contains sequences from the 5′ untranslated region of the mRNA.

This work, demonstrating that particular nucleic acid sequences can be isolated in the absence of any screening procedure other than direct sequencing of the final recombinants, represents something of a triumph for 'brute-force' molecular biology. However, the general applicability of such methods is unclear. Not until the sequencing was quite advanced could Ullrich *et al.* have been confident that islet mRNA did not contain a major component which was not insulin mRNA. It seems likely that if this approach were used in other cases the wrong sequence would be cloned. In this regard it is particularly unfortunate that the paper contains no data bearing on the efficiency of the procedure; it would be of great interest to know how many clones were screened to obtain the four containing insulin sequences.

We can confidently expect these plasmids to be used as probes in experiments to isolate the complete insulin gene together with its flanking sequences from total rat DNA. Once such recombinants are available it will be possible to explore approaches to forcing the expression of the insulin gene within *E. coli.* Techniques already exist to force transcription of inserted DNA, but whether such transcripts can be faithfully translated is unknown. Even if *E. coli* could be persuaded to synthesise preproinsulin there still remains the problem of processing this to the mature hormone. The use of this technology for the large scale production of insulin may well depend not only on engineering *E. coli* to express the insulin gene but on the development of *in vitro* processing systems. There clearly remains a great deal of work before one can confidently anticipate the commercial production of insulin in *E. coli,* but the first step has been taken. ☐

Evidence for Earth expansion?

from Peter J. Smith

The concept of an expanding Earth has been in circulation for several decades now, but has never attracted much interest. If it were not for the historical example of continental drift, it would be tempting to assume that such indifference reflects a correct interpretation of the Earth's behaviour and that expansion is only an illusion in the minds of a handful of enthusiasts. But the temptation should be resisted, at least for the time being. Drift was once regarded as illusory by the majority of Earth scientists; but the idea was kept alive by a few fanatics until proof came at last from outside the field of geology. Geologists, convinced that continental drift was inconsistent with the existing body of geological knowledge, suddenly found their rejected theory confirmed by physicists and were forced to reinterpret their data accordingly.

Of course, it would be dangerous to over-react to history by concluding that the majority must now be wrong about Earth expansion as it would be to reenact the sort of response which greeted Wegener's suggestion that the continents had drifted. The cases are not precisely analogous. There were serious problems with the pre-drift world view that only drift could resolve, whereas Earth expansion appears to offer no comparable advantages. On the other hand, if proof of expansion is to come at all it is most likely to come, as with drift, from the physicists. Earth scientists may feel they have no need for expansion; but if physicists could show that the gravitational constant has decreased with time, expansion would have to be accepted and accomodated.

In the meantime, however, there are still occasional attempts to test the expansion hypothesis against purely geological–geophysical data, the latest of which comes from Steiner (*Geology* **5**, 313; 1977). Steiner's idea is simple in principle. For an Earth of constant radius, the rate at which the surface area of ocean floor increases at oceanic ridges must equal the rate at which it decreases through subduction. But if the former is greater than the latter the total area of the ocean floor must *ipso facto,* increase; and the most obvious explanation of such an increase would be an expanding Earth.

Unfortunately, as previous attempts have shown, the practice of testing for expansion is invariably much more difficult than the principle. Steiner begins well enough with the map of ocean basin ages produced by Pitman *et al.* (*Geol. Soc. Amer. Map MC-6*; 1974), from which he measures directly the area of floor produced in the three major oceans during each geological epoch and period from the Jurassic to the Holocene. The first conclusion to emerge clearly is that at most times the rates of floor production vary considerably from ocean to ocean but with "a tendency toward negative correlations where a maximal rate of sea-floor spreading in one ocean basin is compensated for by a minimal rate in another". During the Paleocene, for example, the rates in the Indian and North Atlantic Oceans were high compared with those in the Pacific and South Atlantic Oceans; during the Eocene the rate in the Indian Ocean was higher than those in the Pacific and North Atlantic Oceans which were in turn higher than that in the South Atlantic Ocean; and so on.

The existence of such negative correlation indicates that sea floor spreading results from a globally coordinated process, although this no more rules out the possibility of traditional convection than it does the possibility of expansion. Slightly more favourable to expansion (though again not definitive), perhaps, is the fact that the combined rate of ocean floor production for all the oceans together has apparently increased exponentially with time since the Jurassic. Of course, this detected increase could be spurious. The ocean floor data currently available would indicate an increase even if the rate of floor production had always been constant, for the older the sea floor the greater generally is the proportion already subducted. Moreover, the picture is confused by the fact that the map produced by Pitman and his colleagues is incomplete, specifying ages for only about 66% of the deep ocean floor. To determine the true rate of floor production since the Jurassic, Steiner has therefore had to make estimates of the spreading in unmapped areas during the past 5 Myr, extrapolate the results back in time, and make corrections for differential subduction. The increase in the rate of floor production with time remains, nevertheless, even when these procedures are complete.

As for numbers, Steiner estimates that the average rate of ocean floor production over the past 165 Myr was $2.61\ \text{km}^2\ \text{yr}^{-1}$. He also concludes that the average subduction rate over the same period was only $1.88\ \text{km}^2\ \text{yr}^{-1}$ and that this average too conceals an increase with time. However, the procedure for obtaining the latter figure is, if anything, even more involved than that necessary to determine the average spreading rate; and therein lie two difficulties. The first is the question of credibility. The greater the degree of assumption, extrapolation and 'correction' there is in calculations of this sort, the less convinced the reader will be of the validity of the result and the greater will be the opportunity for picking holes in the argument. This certainly implies no criticism of Steiner, who has done the best he can with the limited data available. In the circumstances, however, it is bound to be difficult to convince those who are predisposed not to believe in Earth expansion.

The second problem, which may only be a special case of the first, is that the more complicated the procedure and the larger the number of mathematical processes involved, the greater will be the errors on the figures obtained. Thus Steiner estimates the errors to be ±15% on the areal production rate and ±20% on the subduction rate. The obvious conclusion to be drawn from the rates themselves is that over the past 165 Myr the area of ocean floor produced was 33% greater than the area destroyed, which interpreted in terms of an expanding Earth would imply a Jurassic palaeoradius of 5,668 km, or 0.89 of the Earth's present radius. The final error on the palaeoradius, however, is ±13%. Unfortunately, this is just large enough to allow the figures to be interpreted in terms of an Earth of constant radius even though, as Steiner points out, there is good reason for regarding 5,668 km as a maximum.

So Steiner has come up against the problem that has bedevilled most previous attempts to test the hypothesis of Earth expansion, namely, that the basic data have insufficient resolving power. Through no fault of his own, his analysis is unlikely to convert anyone to a belief in expansion, although equally it will do nothing to discourage those already converted. ☐

review article

Quark confinement

R. L. Jaffe*

Nucleons and other subnuclear particles seem to be composed of more fundamental objects, the quarks, but bombardment of nucleons at increasing energy has failed to liberate quarks from the interior of nucleons. This has led to the development of theories in which quarks are of necessity permanently confined. Models of the dynamics of confined quarks, such as the 'MIT bag', have unified our understanding of subnuclear phenomena.

FROM time to time in the past the 'fundamental particles' of physics have been shown to be composites of particles yet more elementary. Molecules are composed of atoms, atoms in turn of electrons and a nucleus, the nucleus in its turn by protons and neutrons. Now there is impressive evidence that protons, neutrons, and the host of short-lived particles with which they interact strongly are composed of yet more fundamental objects called quarks. Quarks, however, have not been found free in nature; and if present theories are correct they never will be: they are thought to be permanently confined to the interior of the particles they compose.

This is a radical departure from the behaviour of other more familiar composite systems. It is relatively easy to separate an atom from a molecule, an electron from an atom or a proton from a nucleus. It is thought not merely to be difficult but actually to be impossible even in principle to remove a quark from inside a proton. This idea is rather young. It has been taken seriously only since early this decade. We have no fundamental explanation of quark confinement, nor an operational description consistent with relativity and quantum mechanics—still the foundations of modern physics. Nevertheless, in the past few years a possible theory of quarks has emerged which is aesthetically attractive and at least consistent with confinement; and an operational model incorporating confinement has been successful in describing many phenomena. Before describing these advances it is necessary to outline the events which forced the extraordinary notion of permanent confinement upon us.

The problem

Today's 'elementary' particles are of two types. There are a few 'leptons'—the electron and neutrino being the most familiar—and the photon, which interact only weakly with one another and with all others. So far these particles have shown no internal structure. They seem to be simple and may be fundamental. Because of their relative simplicity they are useful as probes of the other particles, the 'hadrons', which are certainly extremely complex. Hadrons are defined by the fact that they interact very strongly with one another. The best known are the proton and neutron. The well known effects of nuclear fission and fusion are manifestations of the extremely strong forces between hadrons.

It is the hadrons which are believed to be composed of quarks. In addition to the proton and neutron and the heavier nuclei there are hundreds of known hadrons. All of these others are very short lived. Hope has been abandoned that the hadrons themselves are elementary. Even the proton is not special. It happens to be stable only because there is no lower energy system for it to decay into. In fact the hadrons behave more like excited states of one particle, the hadron, than distinct entities.

With such a host of particles, classification becomes a major task. Hadrons, like atoms or nuclei, may be labelled by their quantum numbers. Examples familiar from atomic and nuclear physics are intrinsic angular momentum (called spin and labelled J) in units of Planck's constant $\hbar$; parity (P), which labels reflection symmetry, and takes values ± 1; and electromagnetic charge (Q) in units where the charge of the proton is $+1$. Quantum numbers are important to the extent that they are conserved by interactions. Charge, for example, seems to be absolutely conserved by all interactions. Hadrons carry other quantum numbers which have been painstakingly discovered over the years: 'baryon number', 'strangeness' and 'charm' are the names of ones of importance to us. Hadrons come in two broad categories: baryons and mesons, which are distinguished by their decays. All hadrons decay by emitting leptons, photons and/or other hadrons, the last of which in turn decay in the same manner. Baryons always leave a proton among their decay products. Their antiparticles, antibaryons, always decay eventually into antiprotons. Mesons either decay entirely into leptons and photons or into baryon–antibaryon pairs. To quantify all this, baryons are assigned 'baryon number' $+1$, antibaryons are assigned $B = -1$, and mesons are assigned $B = 0$. The decay patterns are equivalent to conservation of baryon number. No known interaction violates this conservation law.

The detailed significance of strangeness (S) and charm (C) need not concern us here. It is necessary only to regard them as measurable integer labels carried by hadrons, which are conserved in strong interactions but not in the weak interactions responsible for nuclear beta-decay. Quite early in the game it was observed that strange hadrons ($S \neq 0$) were systematically heavier than non-strange hadrons with otherwise identical quantum numbers. When hadrons with charm ($C \neq 0$) were discovered last year they were found to be heavier still. It is quite possible that there are other even heavier hadrons with other labels which have yet to be discovered. Quantum numbers like charge, strangeness, and charm which distinguish among mesons and among baryons are known generically as 'flavours'.

The proton and neutron have very nearly the same mass (about 938 MeV) and are quite similar in many other respects. They differ, of course, in their electromagnetic charge. All hadrons follow this pattern: they come in (small) families or 'multiplets' with very similar properties but different charges. The explanation (proposed long ago by Heisenberg[1]) is that the strong interactions are to a very good approximation 'charge-blind'. This symmetry, known as 'isospin' symmetry, describes the types of families and the similar properties of members of a family but does not determine which families exist. Why the

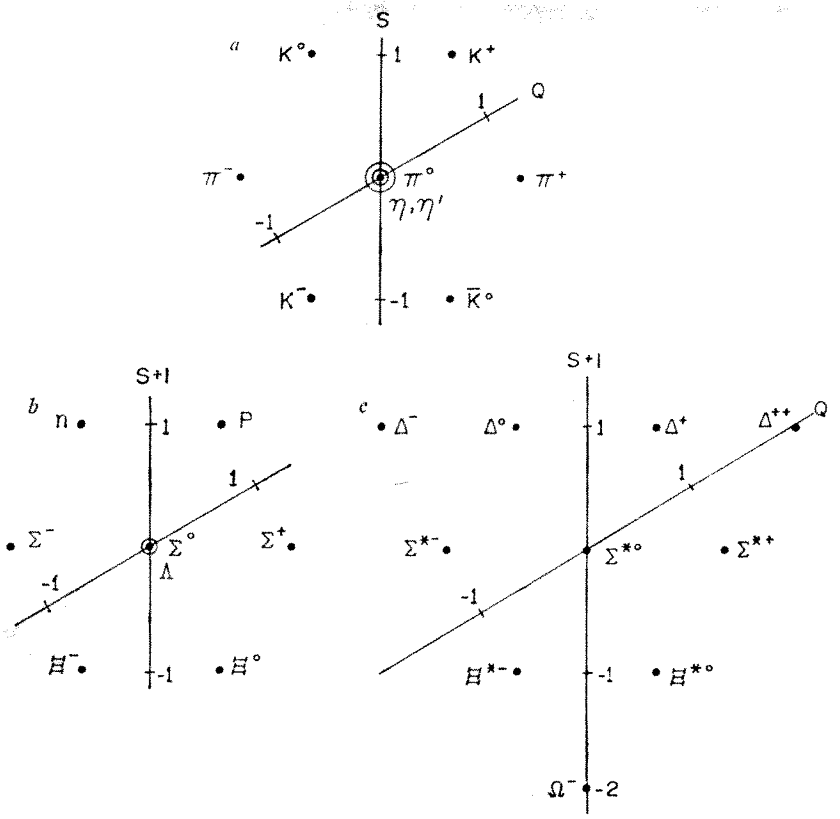

Fig. 1 Hadron multiplets: strangeness is plotted against charge using inclined axes to better display the symmetry. All hadrons in a multiplet have the same intrinsic spin and parity. Within a multiplet states with strangeness are systematically more massive. *a*, 0^- meson nonet; *b*, $\frac{1}{2}^+$ baryon octet; *c*, $\frac{3}{2}^+$ baryon decuplet.

proton–neutron form a doublet, while the π-mesons form a triplet (charges −1, 0, +1), and the Δ-baryons form a quadruplet (charges −1, 0 + 1, +2) is not explained by this observation.

After the discovery of strange hadrons in the early 1950s attempts were made to incorporate strangeness into the classification scheme. The idea was to assign hadrons to families with similar properties (in particular with the same spin and parity) but with different charge and strangeness. Strange hadrons weigh somewhat more than their non-strange siblings so the strong interactions are not blind to strangeness, but they are near-sighted enough to allow us to group particles into families anyway. The correct scheme was discovered by M. Gell-Mann[2] and Y. Ne'eman[3] in 1961. The arrangement of charges and strangeness within a multiplet and the number of states in the multiplet are closely related and are dictated by the mathematical formulation of this approximate symmetry. Some of the most prominent hadron multiplets are shown in Fig. 1. Before the advent of charm in 1976 all known mesons were found to come in multiplets of 9 (nonets) and all known baryons in groups of 1, 8 or 10 (singlets, octets or decuplets).

Still there was no explanation for this apparent multiplet structure. To borrow an anology from atomic physics, the scheme of Gell-Mann and Ne'eman is like the periodic table of Mendeleev. It classifies, but does not explain, the properties of hadrons.

The notion of quarks was introduced in 1964 independently by Gell-Mann[4] and Zweig[5] to explain why baryons come only in multiplets of 1, 8 and 10, and mesons in multiplets of 9. They proposed, for the purposes of classification, to imagine that hadrons are composed of three types of more fundamental particles—quarks[6]. Baryons were to be made of three quarks (Q^3), mesons of a quark and an antiquark $(Q\bar{Q})$. To get the hadron quantum numbers right quarks must have very odd quantum numbers themselves. If the proton is to have baryon number one, then quarks must have baryon number one-third. To give the correct electromagnetic charges for the hadrons quarks must have charges which are 2/3 or −1/3 times the proton's charge. No one has ever observed a particle with fractional charge or baryon number. In 1964 the idea was so radical that most physicists preferred to view quarks as theoretical conveniences—an efficient way of summarising the observed hadrons—not as real objects expected to be observed in the laboratory.

Gell-Mann's three quarks were named u, d and s (for 'up', 'down', names which arose from the formalism of isospin and 'strange'). The quarks' quantum numbers are listed in Table 1. To make mesons combine any quark and antiquark. There are nine combinations with a given total spin and parity just as observed. The quark content of a sample nonet is shown in Fig. 2. Baryons are somewhat more complicated. The families of 1, 8 and 10 are shown in Fig. 3. A bit of tedious mathematics would be required to explain why only these multiplets are allowed. By combining the spins of three quarks it is possible to make multiplets with total spin 1/2 or 3/2. Nature, however, is more selective: the octet containing the proton and neutron has no spin 3/2 counterpart; the spin-3/2 decuplet shown in Fig. 1 has no spin-1/2 analog. What forbids these other configurations? The answer lies in permutation symmetry. The characteristic shared by the allowed baryon configurations is that they are totally symmetric with respect to exchange of any pair of particles. Apparently, then, the quark model must be augmented by the rule that only symmetric configurations are allowed.

This raised a serious puzzle. Long ago Pauli[7] demonstrated a

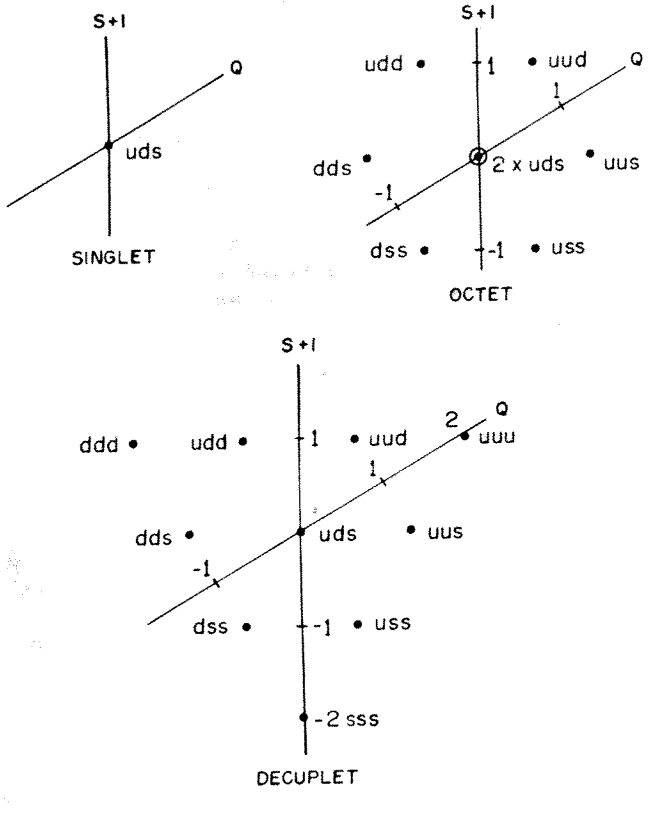
deep connection between symmetry and intrinsic spin: particles with integer spin (in units of $\hbar$) combine with each other only in symmetric configurations while those with half-integer spin combine only in antisymmetric arrangements. Quarks seemed to violate this. Early on this seemed yet another reason not to take the quark idea too seriously. Now it seems to be an essential clue to resolving the mysterious behaviour of quarks. We shall return to it shortly.

Over the years it has proved possible to account for a great variety of phenomena by supposing hadrons to be made of quarks[8]: the magnetic moments of the proton and neutron, photo-excitation of the proton, very high energy scattering of hadrons off one another, to name only a few. The flavour conservation laws observed in strong interactions reduce to the simple rule that the strong force never changes a quark's flavour. The strangeness of a bunch of hadrons is just the number of $\bar{s}$-antiquarks minus the number of s-quarks. Strong interactions may create or annihilate $s\bar{s}$-pairs but the total strangeness is conserved. Weak interactions are flavour changers: in the β-decay of a neutron, for example, ad-quark changes into a u-quark.

Fig. 3 The quark content of a typical baryon singlet, octet and decuplet. Compare Fig. 1*b* and *c*.



The major problem with the quark model was thought to be the failure of attempts to observe free quarks. Originally this was explained by assuming them to be very heavy (say thousands of MeV) and to be bound by very strong forces to make much lighter hadrons like the proton. To remove a quark from a proton would require restoring the binding energy and would be difficult. This is not 'confinement' as we now understand it but just 'binding' as in atomic physics on a grander scale. This picture was difficult to reconcile with the way the model had been applied: quarks were treated as free and light (roughly 1/3 as massive as the proton) and the properties of hadrons were obtained just by adding up the properties of quarks. Interactions generally modify the properties of particles, the stronger the interaction the greater the modification. If the quarks within a proton were bound with binding energy equal to several times their rest mass it seems uncanny that the unmodified quark properties should persist.

Quarks were only 'mathematical' particles anyway. It seemed premature to worry about these dynamical puzzles until someone had actually discovered a quark. During the late 1960s many quark searches were undertaken—none was successful. Finally a series of beautiful experiments[9] led by J. Friedman and H. Kendall of MIT and R. Taylor of SLAC begun in 1967 obtained indirect but persuasive evidence for the existence of quarks within the proton. The MIT–SLAC collaboration scattered high energy electrons off proton targets. The motion of electrons is effected by the local electromagnetic currents within the proton. Electrons do not interact strongly and are relatively structureless. Because of this they make excellent probes of hadrons. The greater the angle through which the electron scatters the shorter distances within the hadron it probes. The experiments showed that when scattered through large angles, the electrons behaved as though scattered elastically from light, spin-1/2 constituents within the proton. This behaviour is known as 'Bjorken scaling' after J. D. Bjorken of SLAC who first suggested such behaviour might be expected[10]. Similar phenomena are well known in other branches of physics[11]. Consider scattering of electrons off a nucleus. At very small angles the electron most often scatters elastically from the nucleus as a whole. At larger angles the scattering is predominantly inelastic, leaving the nucleus in an excited state or fragmenting it into a few pieces. At even larger angles the electron scatters nearly elastically from the individual protons in the nucleus. For this to occur the energy transferred to the proton must be large compared with its binding energy. So the proton is knocked out of the nucleus and could be observed propagating freely after the collision. If the proton had not been independently discovered long before such experiments were performed the behaviour of the scattered electron would have been taken as exciting evidence that the nucleus is composed of weakly bound charge 1 constituents—protons. The neutrons, being electrically neutral, would have been missed.

So it was with quarks. Electron scattering from a nucleus and from a proton are compared in Fig. 4. The observation of Bjorken scaling indicates that there are more fundamental, local bits of charge within the proton. These were called 'partons' by Feynman[12,13]. This series of experiments and subsequent similar neutrino–proton scattering studies suggest that the proton's 'parts' are quarks. In fact there is no serious alternative description of large angle lepton scattering. So hadrons are made of quarks. There might also be electrically neutral quanta (which would not show up in these experiments) to mediate the interactions between quarks. These are known generically as 'gluons', the 'glue' which holds the proton together.

It must be emphasised that the MIT–SLAC experiments showed the proton to be a rather loosely bound collection of quarks. At distances of the order tenths of a fermi within a proton (the proton's radius is about 1 fermi = 10^{-13} cm), there was little if any evidence for forces on the quarks. In short, everything was analogous to inelastic electron scattering off nuclei except that in the nuclear case protons are being knocked out of the nucleus while in our case quarks are not being knocked

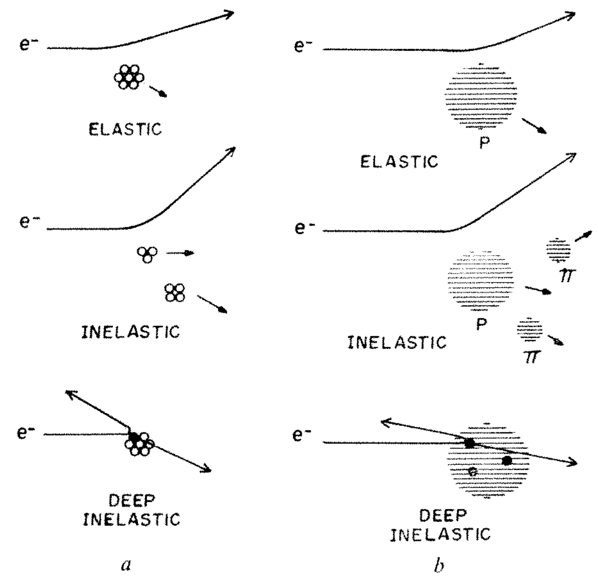


Fig. 4 A comparison of elastic and inelastic electron scattering off a nucleus (*a*) and a proton (*b*). In each case as the scattering becomes more inelastic, it becomes more sensitive to the local charge structure within the target. In case (*a*) when the energy transferred to the nucleus is much greater than a proton's binding energy, the electrons seem to scatter elastically from the individual protons. In case (*b*) the electrons eventually seem to scatter elastically from quarks within the proton.

out of the proton. Hadrons appear to be weakly interacting aggregates of light quarks which nevertheless can never be removed from the interior of the particles they compose.

In the years since the original MIT–SLAC experiments, evidence supporting the quark model has steadily accumulated. During the early 1970s neutrino scattering and electron–positron annihilation have emerged as significant new methods for the study of hadrons. Simple and elegant explanations of the phenomena observed in these new regimes have come from the quark model. Recently hadrons containing a new, heavier quark—the c-quark (for 'charmed')—have been discovered. The mass of the c-quark is thought to be roughly 1,500 MeV. The old quarks are much lighter: the u- and d-quarks may even be massless while the s-quark's mass is about 300 MeV. Because it is heavier the motions of the c-quark are easier to sort out. Quark model enthusiasts have been having a field day predicting (with great success) the properties of new 'charmed' hadrons composed of c-quarks together with the old u, d and s-quarks[14].

The picture of relatively weakly interacting but permanently confined quarks permeates particle physics today. Unfortunately application of the picture to different problems rest on different *ad hoc* assumptions whose relationship to one another is often unclear. It is not a unified picture because we lack a unified theoretical description of confinement. At best, one would like to have a derivation of confinement from some deeper theoretical notions. At least one could hope to have an operational description of confined quarks consistent with the basic requirements of relativity and quantum mechanics. Recently there has been progress in both directions. Many of the ingredients of a fundamental theory of quark confinement perhaps have been discovered. These will be reviewed in the next section. The fundamental work unfortunately remains incomplete because the candidate theory cannot be solved: confinement cannot be demonstrated and the properties of hadrons cannot be calculated.

The theory

We have come very far in understanding the origins of the bizarre behaviour of quarks. The first step towards a solution was the realisation that hadrons possess a secret—a quantum number which is essential in determining quark interactions but which never manifests itself openly in nature. Suppose in the days of atomic physics it had proved impossible to ionise neutral atoms, so only electrically neutral atoms were known. Eventually someone would have guessed that the constituents of atoms carry a hidden quantum number (this should not be confused with a 'hidden variable' which arose in a famous unsuccessful attempt to explain in purely classical terms the indeterminacy usually attributed to quantum mechanical effects)—electrical charge—which dictates the way they are put together in atoms but is never openly manifested in nature. In the case of quarks this hidden quantum number is called colour. It has nothing to do with ordinary visual colour, particle physicists just seem to like familiar names for their rather abstract notions. There are three possible quark colours which we may take to be 'red', 'green' and 'blue'. Each flavour of quark (u, d, s or c) comes in each of the three colours, but hadrons are always combinations of quarks with no net colour. They are colour neutral. (The reader may well wonder how fundamental quarks are now that we have twelve of them. What one calls a new particle is perhaps a matter of semantics. A particle with spin J has $(2J+1)$ different spin orientations which are not considered distinct objects. We likewise may not wish to call each different colour orientation of each flavour of quark a different particle[15]. In any case quarks will be more fundamental than hadrons if their interactions admit a simple, point-like description.)

Colour was originally introduced by Han and Nambu[16] (another early version of the idea is due to Greenberg[17]) to resolve the symmetry mystery mentioned earlier: quarks in baryons seemed to occur only in symmetric configurations although Pauli had shown spin-1/2 particles must occur in antisymmetric arrangements. The solution was simple: the baryons are indeed symmetric in all the observed labels: spin, flavour and spatial configuration, but each quark carries an additional label—colour—and the baryons are antisymmetric arrangements in the colour label. So much for the symmetry mystery. Introducing a new quantum number is risky: the number of possible arrangements of quarks is greatly increased. Should all of these be observed in nature? In fact only a small selection of all conceivable arrangements of colour, flavour, spin and spatial quantum states have been found: all mesons may be classified as a quark and antiquark ($Q\bar{Q}$) of the same colour; all baryons may be classified as three quarks (Q^3) made asymmetrical in colour. Remarkably these are the only combinations of $Q\bar{Q}$ or Q^3 which are colourless. (Certain combinations of coloured quarks have no net colour just as certain combinations of charged electrons and protons have no net charge.) Colour could be introduced into the theory without predicting a vast, unwanted increase in the number of baryons and mesons if accompanied by a rule: all hadrons must be colour neutral.

There is an intimate relation between colour and confinement. A single quark, along with its fractional charge and baryon number, necessarily carries colour. So does any arrangement of two quarks, all of which also have fractional charge. However, a quark and an antiquark, which according to Table 1 have ordinary (integer) charges, also turn out to be the smallest arrangement of quarks with no net colour. The same goes for baryons—groups of three quarks have integer charge and baryon number and, remarkably, may be grouped into colourless configurations. In fact it can easily be shown that any combination of quarks and antiquarks which is colourless also has ordinary quantum numbers. Having learned this we can restate the confinement problem rather elegantly: quarks carry a new quantum number, colour, but for some reason all hadrons are colourless. Quark confinement has been reduced to colour confinement. Quarks must have interactions which select out colourless configurations. The case for colour as it stood in 1973 was summarised rather persuasively by Fritzsch, Gell-Mann and Leutwyler[18], who also proposed a candidate for the actual quark–quark interaction (though the interaction itself seems to have been discovered independently by several workers[19,20].)

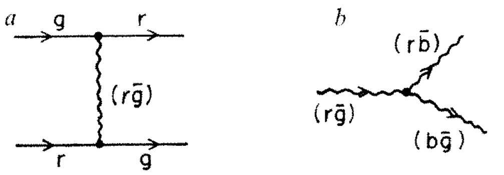

Fig. 5 A sample of interactions in quantum chromodynamics: *a*, red and green quarks scatter by exchanging a quantum of red-greenness; *b*, a red-green gluon emits a red-blue gluon and changes thereby into a blue-green gluon.

The theory of the interactions of electrons and photons, known as quantum electrodynamics (QED), is the most precisely verified theory in science. It is the model for construction of a theory of interactions consistent with both relativity and quantum mechanics. For some years there had been interest in generalisations of quantum electrodynamics known as Yang–Mills[21] theories. QED is based on one kind of charge (electric) interacting with one kind of massless vector field (the electromagnetic field, whose quantum is the photon). In 1954 Yang and Mills formulated a theory of several charges interacting with many vector fields. The novel ingredient was that the vector fields carry the charges (in contrast to QED since the photon is neutral). Thus a particle could change its charge by emitting a field quantum which carries the compensating charge. The theory requires the quanta of the many vector fields to be massless. As in QED there are both electric and magnetic forces between charges. The Yang–Mills theory was not applied to strong interactions during the 1950s and 1960s because there are no massless strongly interacting particles. The possibility of confinement changes all this: the forces between quarks might be of the Yang–Mills type so long as the massless vector quanta (gluons) along with the quarks are permanently confined.

To return to the work of Fritzsch, Gell-Mann and Leutwyler, they supposed that the forces between quarks were of the Yang–Mills type described above. The colour quantum number plays the part of the charge. Quarks interact through colour electric and magnetic fields. With three quark colours it is necessary to have eight massless vector fields—'coloured gluons'. Eight gluons are required in order to maintain conservation of the colour quantum numbers and for all colours to be on an equal footing. A red quark may change into a green quark by emitting a quantum of red-greenness, that is, a red-green gluon. There are nine combinations of colours like red-green, but one combination is actually colourless and does not enter the interaction scheme. Figure 5 shows a sample of the basic interactions of the theory. Because the gluons themselves are coloured they interact with one another much like quarks. This theory turns out to be the only natural generalisation of quantum electrodynamics to a non-trivial group of conserved charges. For this reason it has become known as 'quantum chromodynamics' or QCD.

The case for QCD became compelling later in 1973 when D. Gross and F. Wilczek[19] and H. D. Politzer[20] independently discovered a deep connection between QCD and Bjorken scaling. Generally forces become stronger at short distances. Everyone knows Coulomb's law: $F = e_1 e_2/r^2$ provides a force which increases as charges are brought together. In fact the forces of electromagnetism are even stronger at short distances than Coulomb's law would indicate. At very short distances where relativistic and quantal effects are essential the effective charge, *e*, actually changes. It has long been known that in QED the effective charge increases at short distances. The MIT–SLAC electron scattering experiments however showed that quark–quark interactions become negligible at short distances within the proton. Gross and Wilczek and Politzer found that the gluon-mediated interactions in QCD, do grow weaker at short distances and vanish asymptotically at zero separation as required. No other realistic theory has this property of 'asymptotic freedom'. QCD is singled out as a candidate theory of the strong interactions.

The Yang–Mills theory of coloured quarks and gluons contains all of the ingredients believed to be required of a fundamental theory of the strong interactions. Furthermore it is very precisely formulated. Nevertheless it has not been possible to address the basic question: does this theory lead to the confinement of quarks? The reason for this predicament lies in the deep distinction between formulating a theory of interacting fields and applying it to most physically interesting problems. Theories are formulated 'locally', that is, the nature of the interaction between fields, here quarks and gluons, is specified at an arbitrary point in space and time. Hadrons are, however, extended regions of space in which quark and gluon fields interact with one another constantly. The comparatively simple local interactions can give rise to an arbitrarily complex global structure for a hadron.

Some approximation must be made. Quantum electrodynamics is the only example we have of a theory which is consistent with both relativity and quantum mechanics and for which approximate solutions can be found. The key to approximation is the weakness of the electromagnetic force. The dimensionless measure of its strength is the 'fine-structure constant' $\alpha = \varepsilon^2/\hbar c$ (c is the speed of light, ε is the electronic charge and $\hbar$ is Planck's constant). Since α is about 1/137, things may be calculated perturbatively. To a first approximation there are only free electrons and photons. To next order two electrons have a small probability amplitude ($\sim 1/137$) to interact by the exchange of a photon, and so on. The forces between particles generated in this fashion characteristically fall off with increasing distance. Systems of interacting particles can be assembled by bringing the components together from large distances where their interactions are negligible.

This won't work for a theory of quarks. They are supposed to be permanently confined. There is no sensible limit in which the quarks can be treated as isolated particles. Over very short distances inside a proton quarks interact quite weakly because of 'asymptotic freedom' and a form of perturbation theory can be used to calculate their behaviour. But only a few properties of hadrons are sensitive exclusively to what happens at short distances. Most involve distances of the order of the proton's radius where interactions must begin to become strong if quarks are to be confined. The usual perturbative treatment begins with free quarks and gluons which, if the programme is successful, must miraculously disappear in the finale.

A new approximation scheme is needed. Efforts in this direction have yet to be successful but the attempts themselves have introduced many exciting new ideas into theoretical physics. One approach is to alter the structure of space–time in order to make calculations more convenient. In this work, pioneered by K. Wilson[22] and by J. Kogut and L. Susskind[23], space or both space and time are replaced by a lattice of discrete points. To lowest order quarks sit on a single lattice site. To higher orders quarks move from site to site: the hadron spreads out. It is not difficult to show that in this approach to QCD quarks can never be separated from one another. Of course, space–time is not a lattice. There is evidence for its continuity down to distances of the order of 1/100 the proton's radius[24]. The burden on the lattice approach is to determine whether its predictions are consequences of the original quark gluon theory or artefacts of approximating space–time as a lattice. This dilemma remains unresolved today.

There has been much excitement recently concerning non-perturbative solutions to field equations. Often classical theories of interacting fields admit exact solutions where the field configurations are in no sense small perturbations about the trivial solution—empty space. According to their properties such solutions are known as 'solitons' or 'instantons'. Theories which admit these solutions seem to be qualitatively different from those which do not. Ordinary quantum electrodynamics seems not to. Quantum chromodynamics does, and it is thought that the existence of these solutions is associated with confinement.

An association like this occurs in the theoretical description of magnetic fields in superconductors. When metal in a magnetic field is cooled and becomes superconducting the lines of

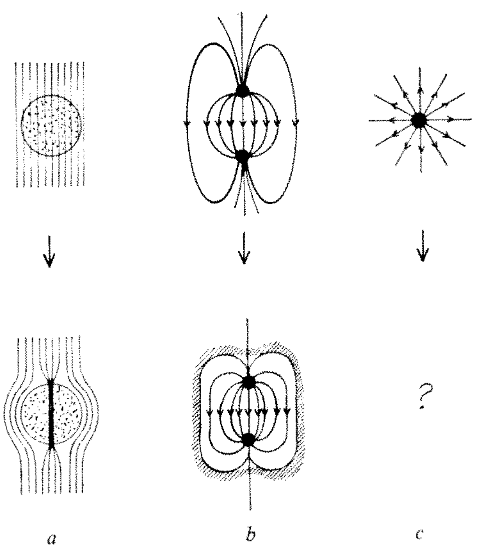

Fig. 6 A superconductor analogy for confinement. *a*, When an ordinary metal in a uniform magnetic field is cooled and becomes a superconductor the magnetic flux lines are excluded from the superconducting region though some may be trapped in 'flux tubes' (Meissner Effect); *b*, quark confinement may be due to a colour-electric Meissner Effect in which the vacuum excludes colour electric flux. A quark–antiquark system is confined to a 'bag' but a single quark cannot exist since its flux lines have no place to end and cannot stretch out to infinite distance.

magnetic flux are expelled from the interior of the superconductor, though some may be trapped within tubes of 'normal' metal within it. This effect, illustrated in Fig. 6*a*, is known as the Meissner effect[25]. The magnetic field lines are, after a fashion, confined. Although this strange behaviour is caused by the interactions of the electrons within the metal, it cannot be obtained by treating them perturbatively. In an ordinary metal electrons move about rather freely much like a gas in a box. In superconductors there is a configuration of interacting electrons which is radically different and lower in energy than the free 'gas' configuration[26]. Since it is lowest in energy it is the preferred (ground) state of the system. All of the bizarre properties of superconductors are attributable to this non-perturbative ground state.

Similar non-perturbative solutions to Yang–Mills theories were found by Polyakov and his collaborators[27]. These and other recently discovered non-perturbative solutions to Yang–Mills theories have excited intense interest. As yet no one has succeeded in establishing a connection between them and the confinement problem. The Meissner effect seems much simpler than QCD.

The analogy with superconductivity can be pushed further. S. Mandelstam has particularly emphasised this point of view[28]. A superconductor expells magnetic flux lines. Suppose empty space (the vacuum) expells colour-electric flux lines. There is a Gauss's law in QCD as in electromagnetism. It requires that lines of colour-electric flux, which begin and end on coloured quarks and gluons, cannot be cut. The colour charge within a given region of space can be measured by surrounding the region with an imaginary surface and counting the number of colour flux lines crossing the surface. If, for some unknown reason, the vacuum expells colour flux lines then all coloured objects and all their attendant flux lines must be confined to some 'normal' region. An isolated quark could not exist since it is the source of flux lines which would have to stretch out for infinite distances. Only configurations with no net colour could exist since they are not required to have flux lines extending to infinity. If this could be shown then QCD would give us an explanation for quark confinement. The 'normal' and 'colour–electric superconducting' states are illustrated in Fig. 6*b* and *c* for a quark–antiquark pair and for a single quark. Perhaps the non-perturbative solutions of QCD will have the effect of making the vacuum behave towards colour–electric flux the same way that a superconductor behaves towards magnetic flux. As present this is merely speculation.

The model

Long before the modern explanation of superconductivity and the Meissner effect were known, Ginsberg and Landau made a model to describe superconductivity without attempting to derive it[29]. Since confinement seems to be at least as hard a problem, my collaborators and I at MIT have taken a similar approach to it[30]. It turns out to be easy to write down a simple and elegant model incorporating confinement. Our approach is more radical than that of conventional quantum field theory. Rather than starting with quarks and gluons everywhere, and then trying to confine them, we start by assigning coloured fields only to the inside of hadrons—since that is where they seem to be. This makes it necessary to distinguish the space inside a particle from that outside it—the hadron must be an 'extended', geometrical object. The shape of a hadron cannot in general be fixed. Rigid objects are not consistent with relativity. If an object is hit at a point on its surface it is not possible for the object to recoil rigidly because other points on the surface would have to have learned of the impact instantaneously. Relativity requires that no information travel faster than the speed of light. Each point on the boundary must be free to move. The equations which describe the motion of the boundary of an extended object must be local in order not to violate relativity.

It is possible to distinguish an otherwise empty region of space in a way consistent with relativity by subjecting the boundary of the region to a constant pressure, B where B may be thought of as a pressure exerted by otherwise empty space on the hadron. There is a simple, classical picture of the dynamics of such an object. A hadron is like a bubble of gas in a uniform, isotropic perfect fluid. The dynamics of a gas bubble is determined by the balance between the external pressure of the fluid and the thermodynamic pressure of the confined gas. A hadron is such a bubble containing only a few quanta instead of the vast number of particles in a macroscopic bubble. Quanta confined to a region of size $-\Delta x$ have—by Heisenberg's uncertainty principle—a momentum $\Delta p \sim \hbar/\Delta x$ and therefore exert a counter-pressure. This quantum pressure keeps the hadronic region open by pushing against the external pressure B. The pressure B fixes the size of hadrons. For protons to be of radius 1 fm (1 fm $= 10^{-13}$ cm), B is required to be about 60 MeV fm^{-3} (or 8×10^{28} atmospheres). This extended region of space is called a 'bag'. Since the model was developed at MIT is has become known as the MIT bag model.

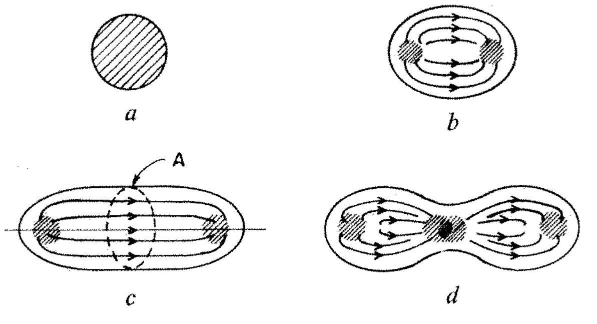
Quarks and gluons are the quanta of coloured fields. What about a one quark bag which would be coloured and have fractional charge? States like this never appear in the model: by construction, colour electric fields, like quarks, exist only inside the bag; but by the analog of Gauss's law, colour electric flux lines must emanate from a bag with net colour. The only consistent solution is for all bags to have no net colour. In fact an infinite energy barrier prevents a colour neutral bag from fissioning into two coloured bags. The situation is illustrated in Fig. 7. Suppose in a colour singlet bag, the colours C and $-$C are separated by a finite distance. The colour electric field lines which connect the charges C and $-C$ exist only in a finite volume V since (in this model) it costs an energy $BV > 0$ to create the space which carries them. Hence at a point between the charges, the fields span a finite cross section A and by Gauss's law, $C = EA$ where E is the mean colour field strength in the cross section. The energy stored in a colour electric field charges as half the square of the field strength, therefore the energy per unit length is $\frac{1}{2}E^2A = \frac{1}{2}C^2/A$. Separating the colours by a distance l costs an energy $\frac{1}{2}C^2l/A$. Fission requires $A \rightarrow 0$ and $l \rightarrow \infty$; it requires an infinite energy to separate colours. Thus colour-, and hence quark-confinement is automatic and comprehensible in this model.

The particular virtue of this approach is that is offers the hope of calculating hadron properties perturbatively[31]. Quarks are arranged into colourless states *ab initio*. The agent responsible for this—a universal pressure—is simple in principle. With such a simple starting point it has proved possible to reconcile some of the apparently unrelated applications of the quark model with one another. Studies of the model reveal two broad classes of hadron which may be called 'spherical' and 'deformed'[32]. Hadrons made of u, d and s quarks with small amounts of angular momentum form spherical bags. To lowest order such a hadron (the proton for example) is a bag of free quarks (as seen in the MIT–SLAC highly inelastic electron scattering experiments)[33]. To next order, the gluon mediated interactions modify the masses and other properties of the hadrons[31]. If, on the other hand, the hadron contains heavy quarks like the newly discovered charmed quark or if it possesses large amounts of angular momentum, it will deform. Deformed hadrons are actually simpler to picture. One is shown in Fig. 7*b*. Consider a meson made of charmed quark and antiquark. Heavy quarks move about less and exert little pressure, but the bag does not collapse around the heavy quarks because they are sources of colour flux lines. The colour fields exert pressure perpendicular to the lines of electric flux. The bag therefore deforms about the flux lines connecting the quark and antiquark. Angular momentum has the same effect; centrifugal force throws quark and antiquark apart and leads to deformation. Light quarks with little or no angular momentum are smeared out throughout the bag. On the average there is no source for colour flux and therefore no axis for deformation.

Detailed calculations of hadron properties have been carried out with the model[31–34]. One example will suffice to illustrate the sort of success which it has had[34]. The masses of spherical hadrons are determined by the quark–gluon dynamics in terms of two fundamental parameters: B, which sets the scale; and a 'coupling constant', α_c which measures the strength of the quark–gluon interaction. The same parameters determine the masses of deformed hadrons although the basic dynamics is quite different. In deformed hadrons the glue is present in lowest order and balances the pressure B, while in spherical hadrons only quarks are present in lowest order and gluon interactions cause small modifications in higher order.

Deformed hadrons have long been known to form families with different angular momentum and mass but otherwise similar properties. In nuclear physics similar families are called rotational bands. In subnuclear physics they are called 'Regge trajectories'. Hadrons on the same Regge trajectory have a remarkably simple relation between mass and angular momentum: $J = \alpha' M^2 + \alpha_0$, where J is the total angular momentum of the hadron, M is its mass and α' and α_0 are called the Regge 'slope' and 'intercept' respectively. One of the best known Regge trajectories is shown in Fig. 8. Experimentally it is found that the Regge slope α' is the same for both baryons and mesons and equals 0.9 GeV^{-2}.

Fig. 7 Hadron dynamics. *a*, A colour neutral spherical meson; *b*, energy is delivered to the meson causing the quark and antiquark to move apart; *c*, colour–electric flux lines connecting quark to antiquark prevent separation; *d*, eventually the energy density in the region between the quark and antiquark becomes sufficient to enable another $Q\bar{Q}$ pair to materialise. These provide new sources and sinks of colour electric field. The system shown in (*d*) will soon fission into two colourless mesons.



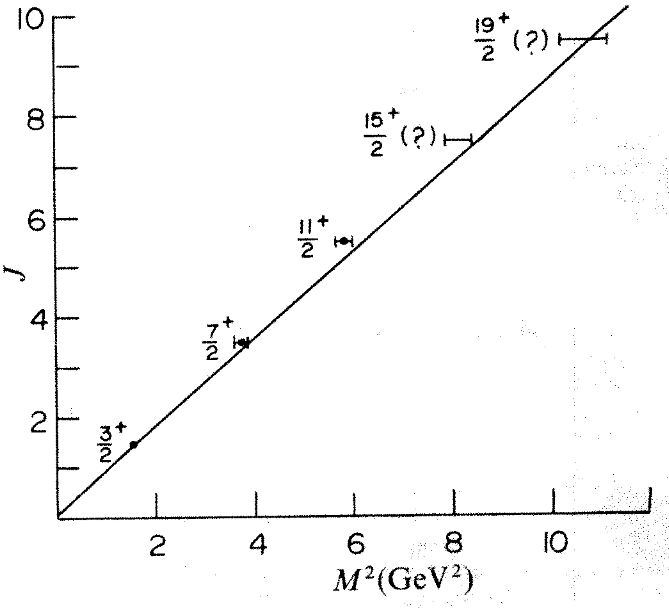


Fig. 8 The Δ-Regge trajectory: the points represent observed hadrons believed to be excitations of the Δ-baryon (see Fig. 1).

In the bag model hadrons with much angular momentum do obey the relation $J = \alpha' M^2 + \alpha_0$ and α' is the same for both baryons and mesons. The universality of α' is natural. The mass of a spinning hadron is determined by a dynamic balance of the gluon field pressure (involving α_c) and the universal pressure B. A spinning meson has opposite colours on either end. A spinning baryon has two quarks on one end and one on the other. The two quarks, however, have antiquark colour in order to combine with the remaining quark to make a colourless hadron. Thus the colour fields in a spinning meson and baryon are the same making α' universal. α' is found to be a simple function of α_c and B. To lowest order: $1/\alpha' = \pi^{3/2}\sqrt{8\alpha_c B}/3$. Remarkably, if α_c and B are adjusted to fit the masses of light, spherical hadrons, then α' comes out 0.88 GeV^{-2}. Two heretofore disjoint aspects of hadron phenomenology are therefore only different reflections of the same underlying physics.

At present the bag model has some important limitations. For example, it is not known whether it can be made consistent with quantum mechanics. All the applications discussed in the literature have made use of a semi-classical approach similar in spirit to Bohr's treatment of the hydrogen atom. In general, relativistic field theories are known to be consistent with quantum mechanics only when studied order by order in ordinary perturbation theory. But as we have noted, perturbation theory has little or nothing to say about confinement. The bag model abandons conventional perturbation theory in search of a starting point closely related to the observed phenomena of confinement. The price seems to be the loss of much of the useful conceptual machinery of quantum mechanics.

Subnuclear physics is in a rather peculiar state at prese
There is wide agreement as to the ingredients in a prospec
theory of hadrons: quarks, colour, gluons and the Y
Mills interaction, to name the most obvious. Yet there

precise, unequivocal and successful calculations of anything to bolster our faith in the theory. In QCD it is not even clear where to begin. If confinement is put in by hand by introducing the bag pressure B then many approximate calculations are possible. The resulting model is especially successful at understanding qualitative features of hadron behaviour. But even having abandoned the attempt to derive confinement one is still left with an extremely complex dynamical system which defies rigorous treatment and quantisation. It is not surprising that our description of hadrons remains in large measure incomplete. Nothing like the permanent confinement of quarks has been encountered before in the study of the structure of matter. Old approximation schemes fail, new ones develop slowly.

What is surprising is the emergence of a candidate theory of hadrons so soon after the realisation that quarks may be permanently confined to the interior of hadrons. It is particularly remarkable since none of the basic ingredients in the theory has ever been observed directly. Instead their existence has been inferred by brilliant and subtle qualitative analyses. The discovery of colour by way of the quark symmetry puzzle and the necessity of gluons and Yang–Mills interactions to understand the paradoxical 'free yet confined' behaviour of quarks are cases in point. The theory which has emerged is very precisely formulated and tightly constrained despite the rather indirect way its ingredients have been established. It offers the hope of explaining hadron properties in precise detail although at present only approximate calculations are possible. It is also very pretty, at least to particle physicists.

The location of the polio genome protein in viral RNAs and its implication for RNA synthesis

Akio Nomoto, Barbara Detjen, Rudy Pozzatti & Eckard Wimmer

Department of Microbiology, School of Basic Health Sciences, State University of New York at Stony Brook, Stony Brook, New York 11794

Evidence is presented that a small protein (VPg) is covalently attached to the 5′-terminal oligonucleotide VPg-pU-U-A-A-A-A-C-A-Gp of the polio genome, to nascent strands of the polio replicative intermediate and to poly(U) of minus strands. A model of polio RNA replication is proposed implicating VPg in initiation of RNA synthesis, possibly as primer.

THE 5′-terminal structure of a ribonucleic acid may reveal mechanisms involved in the biosynthesis of that RNA. For example, the 5′ end of coliphage RNA is a nucleoside triphos- indicating that initiation of phage RNA synthesis occurs genomes of plus strand RNA viruses of eukar- e other hand, are 'capped' at the 5′ end (5′)Np . . . which is a post-transcriptional date, two exceptions to this group are known: f satellite tobacco necrosis virus which termin- G-U (ref. 3), and genome RNA of picornaviruses neither a terminal triphosphate nor a cappin- group. In fact, previous efforts to identify any 5′ end of picornavirion RNA were unsuccessful[4–9]. Recently, we have identified a low molecular weight protein (called VPg) covalently linked to polio virion RNA and have suggested that this protein may be attached to the 5′ end of the genome[10,11]. In this communication we present experimental evidence for the association of the protein with the 5′ end of virion RNA. We also show that VPg is bound to nascent strands of the polio replicative intermediate and to the 5′-terminal poly(U) of polio minus strands. This novel structural feature of poliovirus RNAs permits us to suggest a model of replication which implicates the protein in the initiation of RNA synthesis.

Genome-linked protein VPg at the 5′ end of virion RNA

The location of VPg within the viral genome can be determined by comparing the number of phosphates remaining on the nucleotidyl-protein obtained after digestion of the RNA with the enzymes RNase T2 or nuclease P1. As previously shown, digestion of purified virion ^{32}P-RNA with RNase T2 yields mononucleotides and a small protein of approximately 6,000 molecular weight (called T2-VPg), which is linked to pUp (ref. 11). As illustrated in Fig. 1*a*, this nucleotidyl-protein, [$(aa)_n$-ZpUp, where Z is the hypothetical linkage group between the protein and nucleotide], will contain two phosphate groups independent of its location on the RNA. Nuclease P1 is an endonuclease which yields nucleoside 5′-phosphates[12]. When virion RNA is cleaved at low enzyme concentrations (0.4 mg ml^{-1}, 2 h at 37 °C), the linkage between Z and pU is stable. As illustrated in Fig. 1*a* the nucleotidyl-protein produced by nuclease P1 (P1-VPg) would be predicted to contain only one phosphate if it were terminally bound and at least two phosphates if it were internally bound.

The isolation of P1-VPg can be seen in Fig. 1*b* which shows that the nucleotidyl-protein appears in the flow-through fractions of the ion-exchange column. T2-VPg appears at the same position in this column[11]. P1-VPg and T2-VPg also comigrate by electrophoresis on polyacrylamide gels (for conditions, see ref. 11). Analysis of the number of phosphate groups on P1-VPg required proteolysis due to the affinity of VPg to surfaces[10]. Accordingly, we digested ^{32}P-P1-VPg with Pronase which yielded a single phosphorylated product ^{32}P-P1-Y, with a net charge of −1 at *p*H 5 (Fig. 1*c*). P1-Y is resistant to alkaline phosphatase (data not shown) indicating the absence of a phosphomonoester. Isolation of the proteolytic product of ^{32}P-T2-VPg is shown in Fig. 1*d*. ^{32}P-T2-VPg has a net charge of −2 at *p*H 5 (ref. 11). Half of its label is sensitive to alkaline phosphatase (data not shown). Snake venom 3′-exonuclease yields pUp from T2-Y and pU from P1-Y (Fig. 2*a*, *b*). The data are compatible with ZpU being the structure of P1-Y. We therefore conclude that P1-VPg has the structure $(aa)_n$-ZpU and originated from the 5′ end of the viral RNA (Fig. 1*a*). The covalent attachment of a protein to the 5′ end of genome RNA represents a novel feature in the molecular biology of viruses.

Prolonged digestion of ^{32}P-T2-VPg with Pronase occasionally yielded T2-Y and a by product (T2-Y′) in low yield, which migrates faster than T2-Y during electrophoresis on Whatman 3MM paper. Incubation with aminopeptidase converts T2-Y quantitatively to T2-Y′ (Fig. 3). T2-Y′ yields pUp with snake venom exonuclease (not shown) as does T2-Y and is therefore a derivative of T2-Y from which presumably an amino acid or another ligand has been removed. The structure of T2-Y′ (Z′pUp), which harbours the linkage between VPg and poliovirus genome, is currently under investigation.

Isolation of a 5′-terminal, protein-linked oligonucleotide

To isolate a 5′-terminal fragment produced by RNase T1, we took advantage of the fact that VPg is positively charged as it migrates toward the cathode during paper electrophoresis at *p*H 3.5 or *p*H 7.5 (ref. 10). Thus, the protein-linked fragment would be the only oligonucleotide in an RNase T1 digest whose net charge would be changed by Pronase treatment permitting a 'shift out' experiment originally proposed by Tomlinson and Tener[13]. First, we separated an RNase T1 digest of virion [amino acyl-^{3}H]RNA by ion-exchange chromatography in 7 M urea (data not shown). Tritium counts were found only in a peak containing trinucleotides, an observation suggesting that the 5′-terminal oligonucleotidyl-protein has a net charge of −4. This was confirmed by repeating the experiment with virion ^{32}P-RNA (Fig. 4*a*). Material in peak −4 was desalted and digested with RNase T2 which yielded T2-VPg (Fig. 4*b*). The nature of this T2-VPg was verified by Pronase and nuclease digestion as described in Figs 1*d* and 2*a*. When the material in peak −4 (Fig. 4*a*) was digested with Pronase, a new oligonucleotide with increased negative charge was produced whereas the trinucleotides remained unchanged (Fig. 4*c*). The shoulder of the peak (⩾ −10) in Fig. 4*c* indicated to us heterogeneity of the oligonucleotide, the extent of which changed from experiment to experiment. The material in peak (⩾ −10) was pooled and separated into two spots ('oligo I' and 'oligo II') by two-dimensional gel electrophoresis (data not shown; see ref. 14). 'Oligo I' (which we found to elute ahead of oligo II from the ion exchange column; Fig. 4*c*) and 'oligo II' were recovered from the gel and characterised by further enzymatic analysis (see legend to Fig. 5). Separation of digestion products (Fig. 5) revealed that the oligonucleotides differ only in their amino acyl component resulting from overdigestion with Pronase: the nucleotides of oligo I are linked to Y, those of oligo II are linked to Y′. On the other hand, we repeatedly observed that the amounts of label in the digestion products of the 5′-terminal oligonucleotide disagreed with the expected yields (Table 1). For example, the radioactivity found in Y was

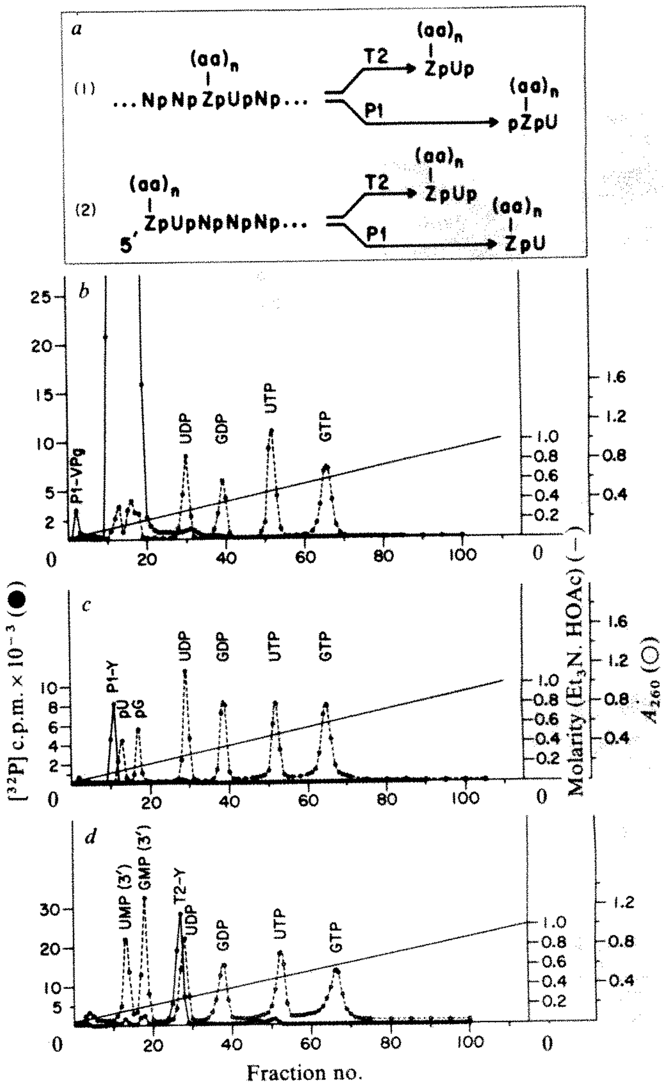

Fig. 1*a*, Hypothetical cleavage scheme for poliovirus RNA. The genome-linked protein may be bound to the RNA (1) internally or (2) terminally through a linkage group Z which has not yet been identified[11]. If internal, Z would be a nucleoside. If terminal, Z could be a nucleoside, one or more amino acids, or any other linkage group. Digestion of the RNA with RNase T2 or nuclease P1 would yield different nucleotidyl-proteins (T2-VPg or P1-VPg) which can be identified through the difference of their phosphate esters. *b–d*, Separation of digestion products of poliovirion RNA by column chromatography at pH 5 in the presence of marker nucleotides. Details as described in ref. 5. *b*, 8×10^7 c.p.m. ^{32}P–RNA were digested with 20 μg nuclease P1 (Yamasa) in 50 μl of 0.05 M ammonium acetate, *p*H 6, for 2 h at 37 °C. 8×10^3 c.p.m. nucleotidyl-protein, P1-VPg, were recovered by lyophilisation which is 52% of the theoretical yield (yield was corrected as explained in Table 1). In other experiments the yield was as high as 75%. *c*, ^{32}P–P1–VPg was digested in 200 μl of 0.05 M Tris-HCl, 5 mM sodium phosphate, *p*H 8, 0.1% sodium dodecylsulphate, with 10 μg Pronase (Sigma Protease type VI) for 20 h at 37 °C. *d*, Digestion of ^{32}P–T2–VPg with pronase as in Fig. 1*c*. P1–Y and T2–Y were recovered by lyophilisation.

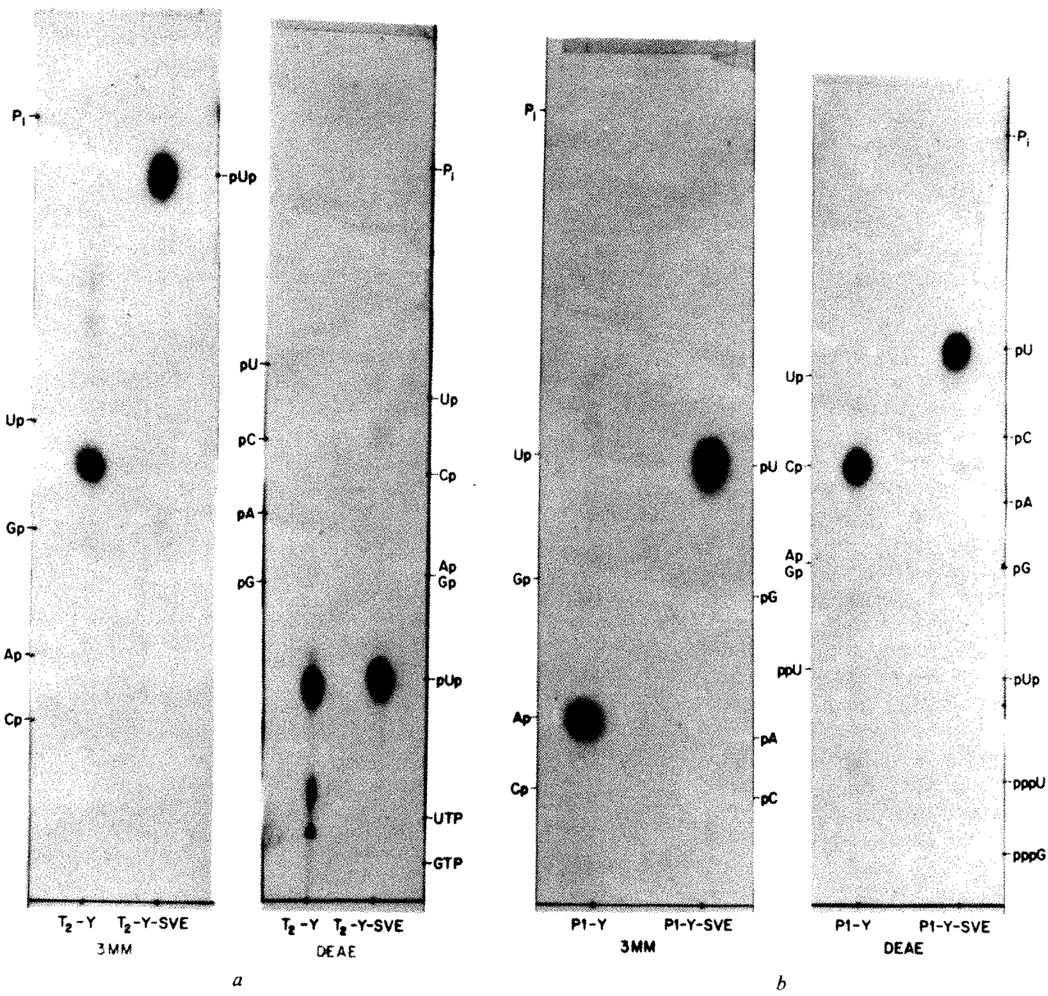

Fig. 2 Paper electrophoresis of ^{32}P-T2-Y and ^{32}P-P1-Y (see Fig. 2*d*, *c*) and their digestion products with snake venom 3′-exonuclease (SVE). *a*, T2-Y and *b*, P1-Y were treated with 0.5 μg purified exonuclease (gift from Dr M. Laskowski, Sr.) in 10 μl 0.02 M Tris-HCl, *p*H 7.5, 0.005 M MgCl$_2$ for 1 h at 37°. Electrophoresis was carried out in 5% acetic acid, adjusted to *p*H 3.5 with pyridine, on Whatman 3MM paper for 1.5 h at 4000 V and on DEAE-paper for 2.5 h at 3000 V. The labelled compounds were visualised by autoradiography. The identity of pUp in *a* and pU in *b* was verified by two-dimensional thin-layer chromatography.

almost twice as high as that found in ApGp after RNase A digestion of oligo II, although both products contain two phosphates (Table 1). The discrepancy can be explained in that the polio ^{32}P-RNA used in our study was not uniformly labelled. This was detected as follows. The base composition of the virion ^{32}P-RNA, when analysed by the isotope dilution method after complete digestion with RNase T2, is Cp = 24.3%, Ap = 30.1%, Gp = 22.5%, and Up = 23.1%, reflecting the base composition of unlabelled RNA[16]. A different base composition, however, is obtained after digestion of the ^{32}P-RNA with nuclease P1 or snake venom exonuclease which yield 5′-monophosphates (pC = 21.2%; pA = 30.5%; pG = 12.7%; pU = 35.6%). These observations suggest that the precursor pools for viral RNA synthesis were not fully equilibrated during growth of the virus. Instead, the specific radioactivity of ^{32}P-GTP and ^{32}P-CTP in the infected cell was lower than that of ^{32}P-UTP. As outlined in Table 1, we have corrected the observed radioactivity of oligonucleotides derived from the 5′ end of polio ^{32}P-RNA for the difference of the specific radioactivity of their individual monophosphates. The corrected values are close to those expected. Based on the cleavage products found and because Y and Y′ contain pUp, we conclude that the 5′ end of the poliovirus genome is homogeneous and has the sequence VPg-pU-U-A-A-A-A-C-A-Gp.

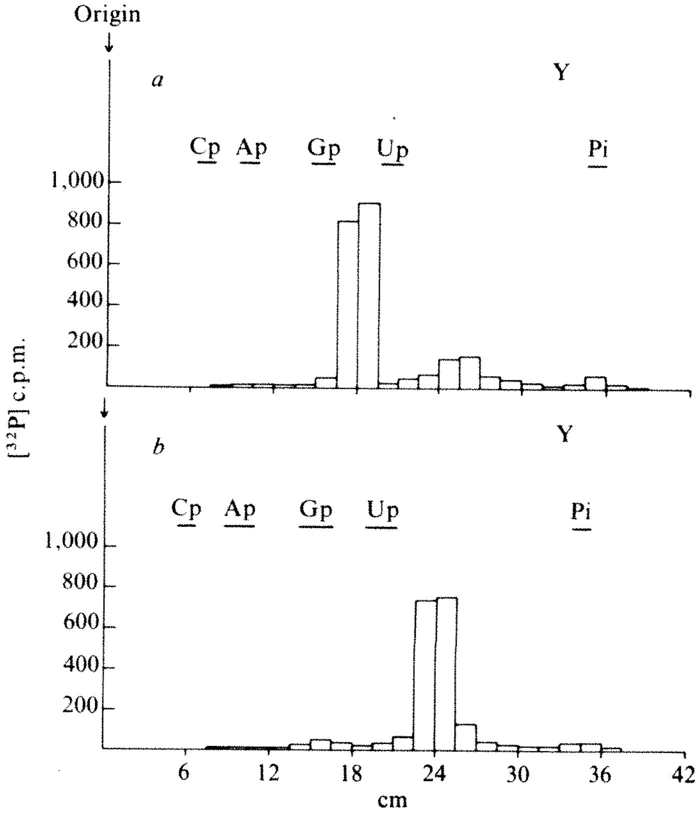

Fig. 3 2.5×10^3 c.p.m. each of ^{32}P-T2-Y (see Fig. 1*d*) were incubated for 2 h at 37 °C, *a*, in 10 μl 0.05 M sodium phosphate, *p*H 8, or *b*, in the same buffer with 0.5 units aminopeptidase M (Sigma). Samples were electrophoresed on Whatman 3 MM paper as described in Fig. 2. 1.5 cm strips of the paper were monitored for radioactivity.

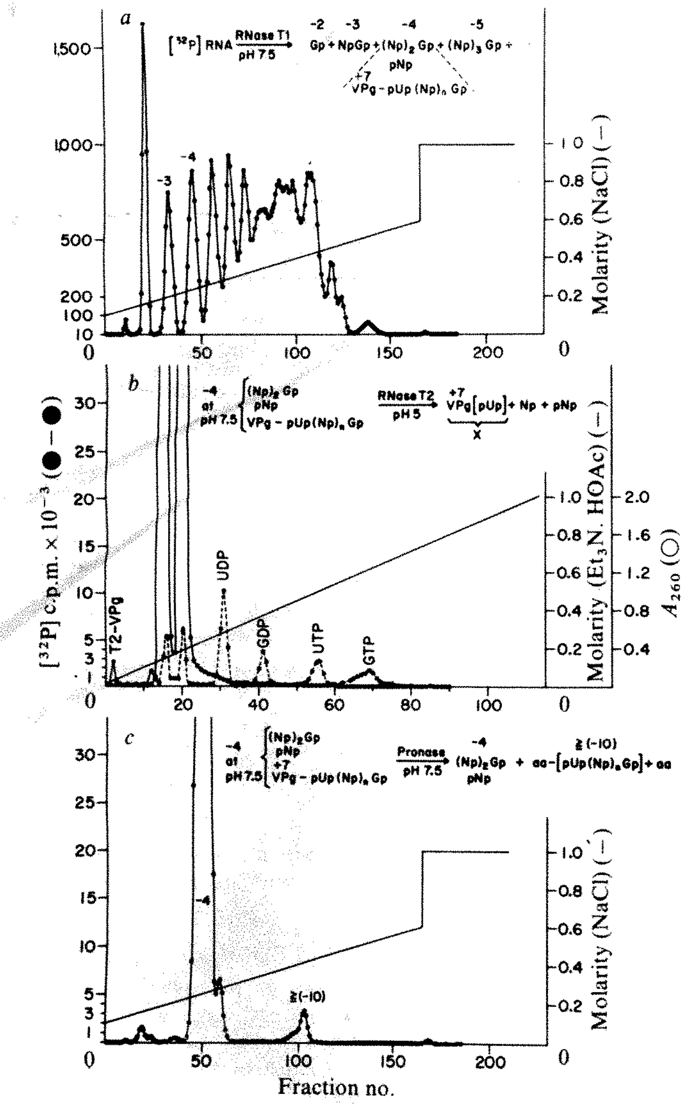

Fig. 4 Isolation of the 5′-terminal oligonucleotide of poliovirion RNA. *a*, 400 μg (4×10^8 c.p.m.) of poliovirion ^{32}P–RNA were digested with 50 units of RNase T1 (Calbiochem) in 200 μl 0.05 M Tris-HCl, *p*H 7.5, 0.002 M EDTA for 2 h at 37 °C. The mixture was applied to a DEAE–Sephadex A25 column and the components eluted with a linear gradient (200 ml) of 0.1–0.6 M NaCl in 0.02 M Tris-HCl, *p*H 7.5, 7 M urea. *b*, Peak −4 of Fig. 4*a* was desalted, digested with RNase T2 and chromatographed on a DEAE–cellulose column in triethylammonium acetate, *p*H 5, as described in Fig. 1*b*. X corresponds to the nucleotidyl-protein T2-VPg. *c*, Peak −4 of Fig. 4*a* was desalted, digested in 50 μl buffer with Pronase as described in Fig. 1*c*, and chromatographed on DEAE–Sephadex as described in Fig. 4*a*. Peak (≥ −10) was pooled and separated into two oligonucleotides ('oligo I' and 'oligo II') by two-dimensional gel electrophoresis (see text).

From the net charge of phosphates of the 5′-terminal oligonucleotidyl-protein (calculated to be −11) and its elution at peak −4 (Fig. 4*a*) we estimate that VPg must have a net positive charge of at least +7 at *p*H 7.5. The positive charge and the affinity to surfaces of polio VPg resemble properties of small nuclear proteins, for example histones of the host-cell. Available evidence suggests, however, that VPg is virus coded as it can be labelled with amino acids 3 h after infection when host protein synthesis is inhibited[11]. Moreover, we have identified a protein linked to genome RNA of another picornavirus, the encephalomyocarditis virus, which was grown in HeLa cells as was poliovirus. The polio-VPg and the EMC-VPg, although isolated from the same host cell, are slightly different in their molecular weights, an observation supporting our notion that the VPg's are virus specific proteins (Golini, A. N. and E. W. unpublished).

VPg is linked to nascent strands of polio RI and to minus strands

The polio replicative intermediate (RI) has been identified as the only structure involved in the synthesis of viral single stranded progeny RNA (see ref. 17 for review). We have, therefore, analysed RI for VPg since the presence of VPg might identify the step in viral replication during which the protein is attached to the viral RNA. ^{32}P–RI was isolated from polio virus-infected HeLa cells as previously described[18]. Absence of free plus strand RNA was shown by gel electrophoresis in 1% Agarose (data not shown; compare ref. 18). Digestion of denatured ^{32}P-RI with RNase T2 and separation of the products by column chromatography as in Fig. 1*b* revealed that the structure does not contain pppNp, ppNp or capping groups (data not shown). Some material eluting at the position of nucleoside diphosphates was analysed by paper electrophoresis and found to contain all 4 pNp's: we assume this material originated from suprious ends in the RI. Material eluting in the void volume was shown to be T2-VPg by (1) subsequent gel electrophoresis, in which it co-migrated with virion RNA-derived T2-VPg, and (2) by digestion with Pronase and snake venom exonuclease which yielded T2-Y and pUp, respectively (data not shown). The number of nascent

Fig. 5 Separation of digestion products by electrophoresis on DEAE-paper in pyridinium acetate, *p*H 3.5 (see Fig. 2) at 3,000 V for 4 h. Oligo I (*a*) and Oligo II (*b*) (see Fig. 4*c*), which had been purified by two-dimensional gel electrophoresis, were digested in 10 μl 0.05 M Tris-HCl, *p*H 7.5, 1 mM EDTA with RNase A for 1 h at 37 °C, or in 10 μl 0.05 M ammonium acetate, *p*H 4.5, 1 mM EDTA with 0.1 unit RNase T2 for 30 min at 37 °C. Oligo II (*b*) was digested in 10 μl acetate buffer, *p*H 4.5, with 0.05 units RNase U2 for 1 h at 37 °C. Radiolabelled compounds were visualised by autoradiography. The identity of oligonucleotides was verified by secondary digestions with RNase T2. Note that digestion with RNase U2 is incomplete in these conditions and yields 2′,3′-cyclic phosphates[15]. For quantitation of the products see Table 1.

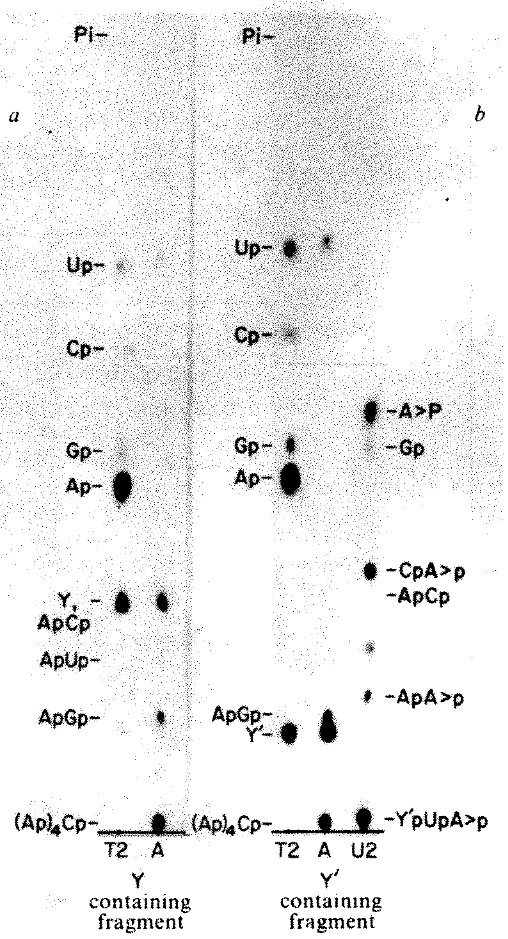

Table 1 Products of nuclease digestion of the polio 5′-terminal oligonucleotide

	RNase T2*			RNase A*		RNase U2*†
Products	Yield (c.p.m.)	Corrected‡	Products	Yield (c.p.m.)	Corrected‡	Products

Cp	534	528	Up	438	434	CA > p
Up	699	692				Gp
						A > p

*Digestion of oligo II and identification of products as described in Fig. 5.

†Digestion with RNase U2 is incomplete. Tle unknown spot was absent in other experiments.

‡The observed counts for each phosphate are corrected for the deviation from uniform labelling of the RNA by multiplying the values with a factor f (f = [% Np in total RNA after RNase T2 digestion]: [% pN in total RNA after nuclease P1 digestion]). For values of base compositions see text. Factors of each 5′-phosphate are: pC = 1.15; pA = 0.99; pG = 1.77; pU = 0.65. For example, the value observed for Y′ (Z′pUp) is corrected by multiplying it with 0.65 since both phosphates originate from pU.

§Assuming that the nearest 3′-neighbour is C. The values are slightly lower if A or U are the nearest neighbours.

strands in RI can be derived from the resistance of the structure to digestion with RNase A (ref. 17). Based on an RNase A resistance of ^{32}P-RI of 36.4%, we calculated that the structure must contain on the average seven nascent RNA strands or 5.5 full length equivalents (the template strand included). This corresponds to 42.3 × 10³ nucleotides assuming 7.7 × 10³ nucleotides per polio virion RNA molecule. 32 × 10⁶ c.p.m. of ^{32}P–RI yielded 12,774 c.p.m. of ^{32}P-T2–VPg. If corrected for the higher than average specific radioactivity of the two UTP-derived phosphates in VPg, these counts correspond to five T2–VPg molecules which is 63% of the theoretically expected value of eight VPg's. Since losses are encountered during the isolation procedures of the adhesive protein[10] we suggest that each nascent strand of polio RI is linked to VPg at the 5′ end.

Evidence for VPg on minus strand RNA was obtained as follows: ^{32}P-RI (ref. 18) or ^{32}P-RF (refs 19, 20) were denatured and annealed to excess unlabelled virion RNA. This removed most labelled plus strand RNA (including the nascent strands) from minus strand RNA[20]. The hybrid double strands were then purified by gel filtration and the 5′-terminal ^{32}P-poly (U) isolated by affinity chromatography after RNase T1 digestion[20]. The poly(U) thus obtained contained in a typical experiment 1 VPg, 45 Up and 1–4 mol of Gp, Cp and Ap. Presence of bases other than Up would be expected[20]. The low levels of Gp, Cp and Ap, on the other hand, clearly indicate absence of contaminating plus strand RNA. The yield of ^{32}P-VPg, however, is higher than expected since the average length of poly(U) has been reported to be 60–90 nucleotides[18–20]. We have, at present, no explanation for the high yield. ^{32}P-VPg was isolated from ^{32}P-poly(U) by column chromatography as described in Fig. 1*b*. It had the same mobility in polyacrylamide gels as virion RNA-derived VPg and yielded after digestion with Pronase and snake venom exonuclease T2-Y and pUp, respectively (data not shown). We conclude that polio minus RNA is linked at the 5′ end to a small protein. This explains our previous failure to transfer phosphate with polynucleotide kinase to the poly(U) of phosphatase treated polio minus RNA[20].

The absence of terminal triphosphates and the presence of VPg on nascent strands of polio RI is direct evidence not previously reported that synthesis of poliovirus RNA occurs from 5′ to 3′. It also suggests that VPg may be involved in an early step of RNA synthesis.

Possible role of VPg in replication

Our previous failure to find pppNp in digests of polio RI suggested to us that initiation does not occur *de novo* but by an alternative mechanism, possibly by a primed reaction (see discussion in ref. 5). The5 ′-terminal structure of polio virion RNA, of nascent strands in polio RI, and of polio minus strand RNA, which we report here, implicates a most unusual molecule for the role of a primer in RNA synthesis: a small, basic protein. Our current view of the role of that protein, VPg, in replication

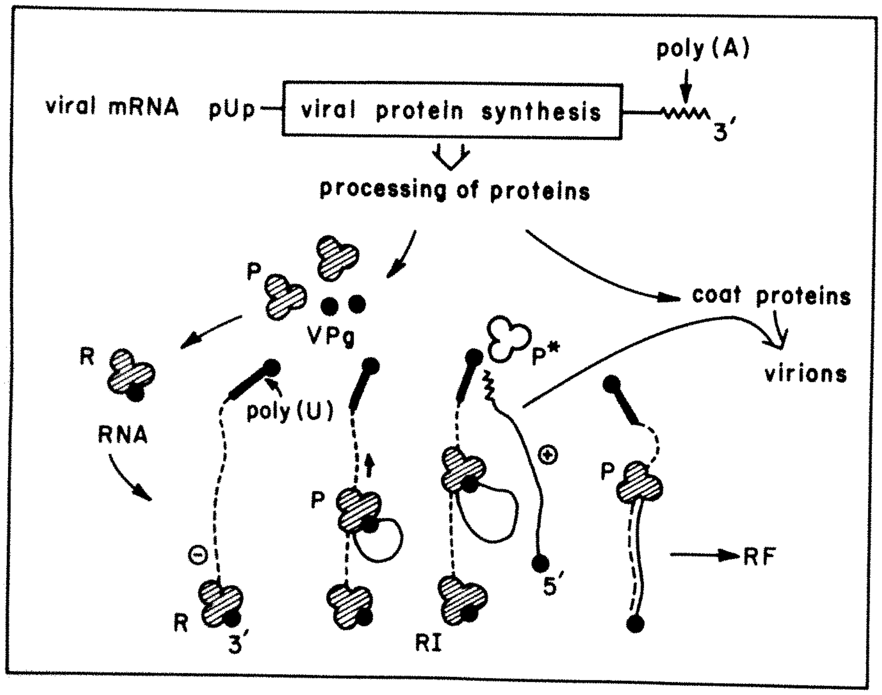

Fig. 6 Involvement of the genome-linked protein VPg in polio virus RNA synthesis. The model shows only synthesis of plus strands but applies also to synthesis of minus strands. RI, replicative intermediate; RF, replicative form (double stranded RNA); R, replicase; P, polymerase.

is illustrated in Fig. 6. Following the post-translational cleavage of viral proteins (see ref. 21 for review), newly made VPg associates with newly made protein P (a hypothetical, virus-specific RNA polymerase) to form the replicase R. Replicase R, but not polymerase P, is able to initiate plus or minus strand synthesis whereby VPg is linked to the nascent RNA. Strand elongation will then proceed during which the RNA-linked VPg remains attached to the polymerase. This condition would prevent the nascent strand from annealing to the complementary template RNA. After the transcription of RNA and its 3′-terminal poly(A) (ref. 22) has been completed, progeny strands and polymerase P* are released. The released polymerase P* may or may not be competent to reassociate with free VPg and re-enter the replicative cycle. It should be stressed that VPg could enter the replication complex also in form of the peptide chain of a precursor protein. Initiation of RNA synthesis may then occur concomitantly with proteolytic cleavage of the precursor yielding a nucleotidyl-protein.

Should the RNA-linked VPg dissociate from polymerase P after initiation of RNA synthesis, strand elongation will occur in the absence of the 'initiator' protein. As a consequence the nascent strand may anneal to the template RNA thus generating double-stranded RNA, the polio RF. In fact kinetic studies[17] and biochemical studies[19] have shown that polio RF is a by-product of replication and not an artefact of isolation procedures.

A tight coupling of poliovirus RNA synthesis to viral protein synthesis exists throughout the infectious cycle even though the sites of translation and replication are physically separated[17]. Our model offers an explanation for this control mechanism: the attachment of protein VPg to RNA requires that VPg be continuously supplied by the translational machinery.

Finally, one striking finding is that the viral mRNA is not identical to virion RNA as previously assumed[17] in that it lacks VPg. Instead, polio mRNA is 5′-terminated with pUp[5-7]. This requires that VPg be cleaved from infecting virion RNA. To what extent this type of 'processing' occurs—cleavage of just the protein or of an oligonucleotidyl-protein—will be known when we have identified the 5′-terminal nucleotide sequence of viral mRNA. Removal of the positively charged protein could be obligatory for translation and might, at the same time, render viral mRNA incompetent for encapsidation. In fact, mRNA is not a precursor for virions[17] which might implicate VPg in the morphogenesis of the virion. It should be mentioned that the protein is not essential for virion RNA to be infectious since RNA from which VPg has been removed proteolytically fully retains its specific infectivity (Golini, A. N. and E. W., unpublished).

We thank Ann Jacobson, Joseph Kates, and Fred Golini for criticisms, Paul Rothberg for help in identifying VPg on minus strands and Nancy Reich for technical assistance. This work was supported in part by grant CA-16879 from the US NCI, DHEW, and by grant BMS 75-05378 from the NSF.

Purification and structural characterisation of human *HLA*-linked B-cell antigens

Timothy A. Springer, James F. Kaufman, Cox Terhorst & Jack L. Strominger

Harvard University, The Biological Laboratories, 16 Divinity Avenue, Cambridge, Massachusetts 02138

The human B cell-specific alloantigen which is closely linked genetically to HLA *contains two non-covalently associated, sialogycoprotein subunits of molecular weight (MW) 29,000 (p29), and 34,000 (p34). Although p29 and p34 have different amino-terminal sequences, their tyrosine peptide maps indicate considerable similarity in other portions of their polypeptide chains. Thus the genes for their proteins may have evolved by duplication of a common ancestral gene. Another lymphocyte cell surface protein of MW 16,000 (p16) has also been characterised. Both p16 and p44 (the heavy chain of HLA-A,B antigens) have been compared with p29 and p34.*

A HUMAN system of cell surface alloantigens has recently been identified which is expressed predominantly on B lymphocytes, and is determined by a gene in *HLA* (refs 1–4), the major histocompatibility complex (MHC) of humans. At least two genetic loci for B-cell alloantigens have been identified in the *HLA* region separable by crossing over[5]. One of these loci is either identical to or in very strong linkage disequilibrium with the *HLA*-D locus, the genetic locus causing the strongest stimulation of the mixed lymphocyte culture (MLC) (ref. 1). Human *HLA*-linked B-cell antigens are serologically distinct from the cell surface antigens which are products of the classical *HLA*-A and *HLA*-B loci. It has previously been shown that papain solubilised and purified *HLA*-linked B-cell alloantigens consist of a complex of two polypeptides of 23,000 (p23) and 30,000 (p30) molecular weight (MW) (refs 6–8). Antisera raised against this complex are potent inhibitors of the MLC reaction and precipitate polypeptides of 29,000 and 34,000 MW (refs 6–9) from detergent-solubilised extracts.

This report describes the isolation of detergent soluble *HLA*-linked B-cell alloantigens, analysis of their subunit structure, and characterisation of the subunits by amino acid analysis, NH_2-terminal sequencing, and peptide mapping.

Purification

Membranes were prepared from RPMI 4265 lymphoblastoid cells, solubilised with the non-ionic detergent Brij 99 : Brij 97 (2 : 1), and after high speed centrifugation, the detergent soluble supernatant was adsorbed on to and eluted from a *Lens culinaris* lectin affinity column[10,11]. The eluate was subjected to gel filtration on a BioGel A-5m column (Fig. 1). Fractions from the area of the column containing protein were analysed by sodium dodecyl suphate (SDS) gel electrophoresis (Fig. 1, inset) and placed in pools A, B and C. The material applied to the BioGel A-5m column consisted predominantly of six polypeptides of MW 105,000 (p105), 44,000 (p44), 34,000 (p34), 29,000 (p29), 16,000 (p16), and 12,000 (p12). p105 and p16 were in a sharp peak at 900,000 MW (pool A), and p44 and p12, the subunits of HLA-A,B antigens, were in a sharp peak at 400,000 MW (pool C) with some aggregated p44,12 at higher MW. p29 and p34, which are the subunits of the *HLA*-linked B cell alloantigen (see below), chromatographed at an intermediate MW in a broad peak indicative of partial aggregation (pools A and B) and were largely separated from p44,12. The fact that the ratio of p29 to p34 was constant in all fractions of the column was consistent with non-covalent association between p29 and p34. Membrane suspensions were prepared in the presence or absence of 1 mM dithiothreitol (DDT) (refs 13, 14). The preparations with no DDT were somewhat less pure, but p29 and p34 showed a similar elution pattern during BioGel A-5m filtration.

Subunit structure

After preparation in the absence of DDT, the fractions from BioGel A-5m filtration enriched in p29 and p34 were incubated with 0.6% SDS at various temperatures, in the presence of iodoacetamide (IAA) or 2-mercaptoethanol (ME) and electrophoresed on SDS gels (Fig. 2*a*, *b*). Comparison of the patterns at different temperatures showed that the HLA-A,B antigen subunits, p44 and p12, were dissociated and electrophoresed identically after incubation at all temperatures. But, after incubation at 21, 27 or 38 °C in SDS, p29 and p34 were associated in a complex (p29,34) at an apparent MW of 55,000, but were dissociated at 100 °C. Interestingly, when pooled human IgG was similarly treated with ME and SDS at 21 °C, L chains were dissociated, but H chains remained associated non-covalently (at the ME concentration used[15]) in an H_2 dimer which calibrated at 90,000 MW (Fig. 2*d*). Since dissociation into p29 and p34 occurred at 100 °C in the presence of 10 mM iodoacetamide to prevent disulphide interchange (Fig. 2*a*), it may be concluded that p29 and p34 are not linked by disulphide bonds. The mobilities of the subunits in reduced gels (Fig. 2*b*) were different from those in unreduced gels (Fig. 2*a*), particularly in the case of p29. The identity of reduced and unreduced bands was confirmed by cutting out bands from unreduced gels, reducing and electrophoresing them. Two dimensional SDS gels of the same preparation using electrophoresis without reduction in the first dimension, followed by reduction and electrophoresis in the second dimension, also showed that while p44 disulphide-linked dimers were present in these preparations, p29 and p34 were not disulphide-linked (see Fig. 7 in ref. 13 and Fig. 2 in ref. 14). But, cross-linking experiments with two cleavable cross-linking reagents containing S–S bonds[16,17] and isoelectric focusing showed that p29 and p34 are non-covalently associated with each other and that dimers of p29 alone or of p34 alone are not present (see Figs 3 and 4 in ref. 18).

Purified p29,34 was prepared by incubation of pool B in SDS at room temperature, followed by preparative SDS gel electrophoresis. Immunisation of rabbits with this material elicited a B cell specific antiserum with properties much like the B cell specific anti-p23,30 heteroantisera reported previously (refs 6–8, 18; T.A.S., J.F.K. and A. Fuks, in preparation). Moreover, purified p29,34 antigen specifically inhibited an *HLA*-linked B cell alloantiserum Po[41]. Heat-dissociated p29 and p34 did not elicit a detectable antibody response in rabbits and did not inhibit either the human alloantiserum or the rabbit heteroantiserum prepared against the p29,34 complex.

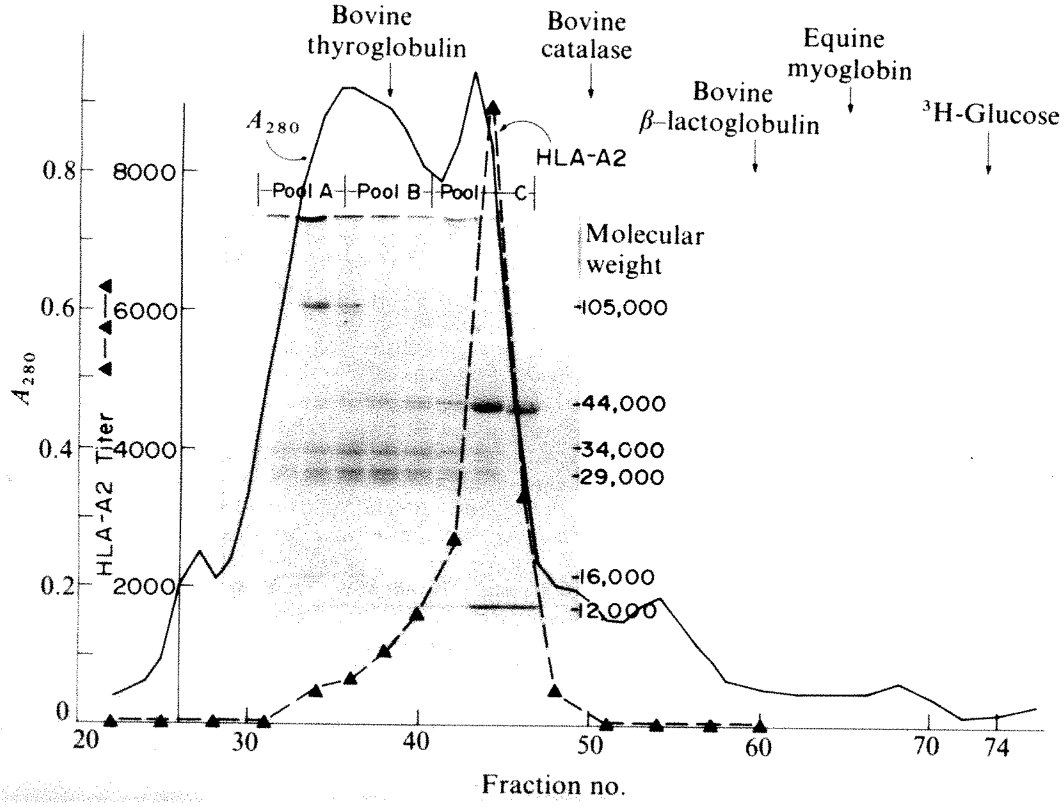

Fig. 1 BioGel A-5m filtration and SDS gel electrophoresis profile of p29,34. BioGel A-5m filtration of the lectin column eluate was as described[10,11]. Equal volumes of the even numbered fractions 30–48 were precipitated with five volumes of acetone and electrophoresed on Laemmli 11% polyacrylamide–SDS slab gels[12], after boiling in 5% ME sample buffer, and in the figure are aligned with their respective BioGel fractions.

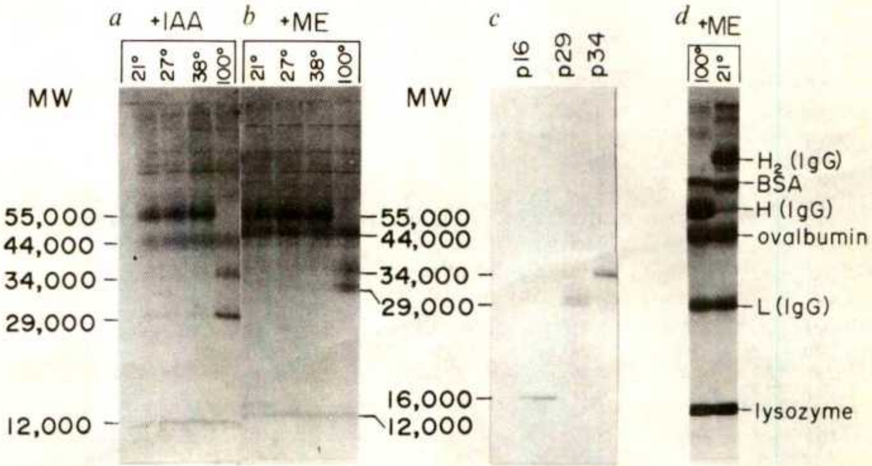

Fig. 2 SDS gels of p29,34 preparations after various treatments. *a*, SDS gel electrophoresis in 10% acrylamide Laemmli gels[12] of material purified in the absence of DTT by lectin affinity chromatography and gel filtration[13,14] after incubation with 0.6% SDS and 10 mM IAA for ½ h at 20, 27 and 38 °C or for 5 min at 100 °C. *b*, As above, except incubation was in the presence of 5% ME instead of IAA. *c*, 2 μg of each polypeptide eluted from gels[19] was electrophoresed in an SDS7–15% acrylamide gradient gel. *d*, A mixture of standards (IgG, bovine serum albumin (BSA), ovalbumin, and lysozyme) were electrophoresed after treatment as in (*b*).

Chemical characterisation

The subunits of the *HLA*-linked B-cell alloantigen, p29 and p34, as well as p16, an unrelated protein which also bound to *Lens culinaris* lectin affinity columns and was obtained in good yield, were chemically characterised.

Materials in pools A and B were combined, alkylated with 3 mM iodoacetic acid and heated at 100 °C in the presence of SDS. Proteins were then purified by preparative electrophoresis in 0.8×22 cm, 10% polyacrylamide tube gels using precautions described by Weiner *et al.*[19]. Advantage was taken of the greater separation of p29 and p34 in the unreduced state (see Fig. 2*a*). After elution, the proteins were chromatographed twice on a 0.9×40-cm Sephadex G-50 column equilibrated with 20 mM NH_4HCO_3 to remove SDS and substances which interfered with the Edman degradation, and were lyophilised for amino acid and NH_2-terminal sequence analysis. Equimolar amounts of p29 and p34 were recovered, as measured by either the Lowry assay[20] or amino acid analysis. Analytical electrophoresis of the eluted polypeptides (Fig. 2*c*) showed them to be homogeneous.

The peptides were also shown to be homogeneous by amino-terminal analysis using the SDS–dansyl technique[19] and by automatic amino-terminal sequencing (Table 1). The amino-terminal sequences of p29 and p34 are quite different from one another, and from p16. Strikingly, the NH_2-terminal amino acids of p29 and p34 are identical to those of p44 and p12 (refs 11, 21, 22) although no further homologies are obvious. Much more extensive sequence data for all of these polypeptides will be required to examine the possibility of homology among them.

The amino acid compositions of p16, p29 and p34 were determined by performing hydrolysis for 24, 48 and 72 h and applying samples at two concentrations to a Beckman 121 M analyser equipped with a microbore single column system (Table 2). The composition of p44 from detergent soluble HLA-A,B antigens (a mixture of three specificities)[10,11] is included in Table 2 for comparison. The amino acid compositions of p29 and p34 are strikingly similar, suggesting that these proteins may be related. The amino acid compositions showed that p29 and p34 do not contain an unusually low percentage of polar residues, suggesting that only a short segment of their polypeptides is involved in membrane binding. This is consistent with the finding that papain-solubilised *HLA*-linked B cell alloantigens (p23,30) contain polypeptides of only slightly shortened length[6–8].

The sialic acid content (Table 2) was 2.2 and 2.6 mol per mol for p29 and p34 respectively, and thus they are both sialoglycoproteins with amounts of sialic acid similar to that of HLA-A,B antigen heavy chains[21]. Staining of SDS gels with periodic acid-Schiff reagent (PAS) also showed that p29 and p34 are glycoproteins. Since glycan moieties which have affinity for the *Lens culinaris* lectin are generally linked by a glycosylamine bond to asparagine and are branched oligosaccharides with galactosyl-*N*-acetylglucosamine sequences in the outer chains and mannose residues in the core[26], the carbohydrate compositions of p29 and p34 may be similar to that of p44 (ref. 21). p16 contained 0.5 mole sialic acid per mol, but PAS staining was not detected.

Since p29 and p34 are glycoproteins, their true MWs may be lower than the MW estimated by SDS gel electrophoresis, as is the case for the heavy chain of HLA-A,B antigens[21]. Using these molecular weights as a starting point, the peptide MWs of p29, p34 and p16 were calculated from the amino acid compositions[27] and found to be 23,600; 28,400; and 15,600 respectively, and the latter MWs were used for calculation of amino acid composition in residues per molecule (Table 2). Three cysteines were found in p29 and p34 (although cysteine may have been underestimated since p12 contained 0.8 residue per mol). p29 and p34 which had been treated with 1 mM DTT and 3 mM iodoacetic acid in the absence of SDS in order to alkylate easily reduced S–S bridges and free SH groups, were also analysed. They contained 0.8 and 1.0 residue of

Table 1 Amino terminal sequences

	Residue

Peptides (10–30 nmol) were sequenced using ^{35}S-phenylisothiocyanate (New England Nuclear) in an updated Beckman 890 B Sequencer[21]. Phenylthiohydantoins were identified after thin-layer chromatography on polyamide sheets by visual inspection and autoradiography. Arginine, lysine, isoleucine and leucine were identified on the amino acid analyser after back hydrolysis. Peptides were also sequenced using the SDS–Edman–dansyl technique[19].

carboxymethyl-cysteine per mol respectively. The additional cysteines of p29 and p34 were either in intrachain disulphide bridges or unreactive. The fact that the mobilities of p29 and p34 in SDS gels (Fig. 2*a*, *b*) are slower after reduction suggests that they each contain at least one intrachain disulphide bridge. Even during purification in the absence of DDT, as shown above the easily alkylated cysteines are not oxidised to form interchain disulphide bridges between p29 and p34.

Subunit homologies in tryptic peptide maps

Although limited NH_2-terminal sequencing did not reveal homology between p29, p34 and p44, homologies between polypeptides of dissimilar size do not necessarily begin at the NH_2-terminus. Since the amino acid compositions suggested such an homology, these proteins were compared by tyrosyl peptide mapping.

Carboxymethylated p16, p29, p34 and p44 were heated at 100 °C in the presence of SDS and labelled with ^{125}I. After removal of SDS, they were digested with trypsin[28]. Comparison of the ^{125}I-tyrosine tryptic peptides by one-dimensional silica-gel chromatography (Fig. 3*a*) showed that p29 and p34 had an almost identical peptide pattern. Spots due to free iodine, present in all samples, migrated close to the solvent front in the one dimensional system (and moved out of the area shown on the two dimensional maps illustrated in Fig. 3*b*). Two-dimensional maps (Fig. 3*b*) showed that p29 and p34 shared six major ^{125}I-tyrosine tryptic peptides (labelled A and B). p29 and p34 also each seem to contain unique peptides (labelled C and D) which agrees well with amino acid analysis showing p29 and p34 to contain eight and seven tyrosines, respectively. p44 showed considerable differences but seemed to contain one peptide (A) in the same position as a peptide of both p29 and p34. No significance should be attached to this single similarity without much further study. p16 showed no homology with

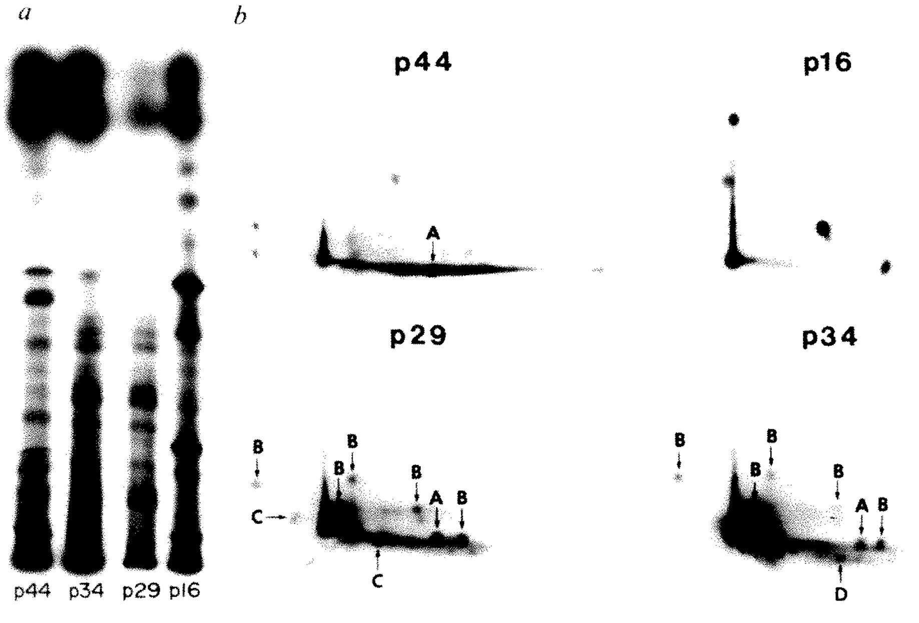

Fig. 3 ^{125}I-tyrosine-labelled tryptic peptide maps of p16, p29, p34 and p44. Peptides were labelled with ^{125}I in the presence of SDS, digested with trypsin, and separated on silica gel G (ref. 28). HLA antigens were prepared as described in refs. 10 and 11 and p44 was separated from p12 by preparative SDS gel electrophoresis[19]. *a*, Chromatography dimension only. *b*, Chromatography (upward) followed by electrophoresis (anode to right). The origin is the intensely radioactive spot near the lower left corner. Labelled spots: A, peptides common to p29, p34 and p44; B, peptides common to p29 and p34; C, peptides unique to p29; D, peptide unique to p34.

any of the other peptides and provided evidence that none of the homologies observed in two-dimensional maps were due to artefacts. Thus p29 and p34 are highly homologous to one another. p29 and p34 could not be proteolytic products of p44, since four peptides not present in p44 were found in p29 and p34. Several pieces of evidence show that p29 is not a proteolytic breakdown product of p34. p29 contained one more serine and tyrosine than p34 (Table 2) and two unique tyrosine tryptic peptides (Fig. 3). Additionally, p34 contained a tyrosine residue at position 13 (Table 1), and therefore, proteolytic cleavage from the NH_2-terminus would have produced a product containing two fewer tyrosines than actually found in p29. Proteolysis of p29 and p34 during preparation or storage was never noted, and the ratio of the two polypeptides always remained constant, as determined by SDS gel electrophoresis. Equimolar amounts of p29 and p34 were recovered after preparative SDS gel electrophoresis. Proteolysis would have been expected to result in a mixture of molecules of $(p34)_2$, $(p29)_2$ and $(p29)_1(p34)_1$ structures, but only molecules of the latter structure were found in cross-linking experiments. p29 and p34 each also seemed to be uniquely cleaved by papain digestion, since one polypeptide was converted to p23 and the other to p30. Recent studies of somatic hybrids have also suggested that p29 and p34 are products of different genes[29].

Two likely explanations for the high degree of homology between p29 and p34 remain. A common portion could be encoded by one gene, and unique portions, probably at the NH_2-terminus could be encoded by different genes (a two gene, one polypeptide model, as in antibodies). Alternatively, the genes for p29 and p34 could have arisen by duplication of a common ancestral gene. Since this is the case for two other genes in *HLA*, *HLA-A* and *HLA-B* (ref. 21), this seems a likely explanation. Inhibition of the alloantiserum suggests that at least one of the p29 and p34 subunits is a product of one of the *HLA* gene loci which code for B cell alloantigens. But, since genes which code for homologous subunits are often unlinked (as is the case for the immunoglobulin L and H chain genes[30]), p29 and p34 would not necessarily both be products of the *HLA* region.

If the tyrosine tryptic peptides are representative of the remaining three-quarters of the tryptic peptides of p29 and p34, these molecules would be identical throughout most of their sequences. It will be interesting to determine by further structural analysis whether non-covalent association occurs between homologous regions, and whether differences between the subunits are confined to the NH_2-terminal region. Since RPMI 4265 cells may be heterozygous, and in analogy to the mouse *I* subregions[31], closely linked loci might specify chemically similar yet distinct molecules, p29 and p34 preparations may well contain chemically different populations of molecules, which might explain the electrophoresis of p29 as a doublet in high resolution Laemmli SDS gels (Fig. 1). Such differences must be limited, however, as no obvious heterogeneity was detected by NH_2-terminal sequencing and close to the expected number of major tyrosine tryptic peptides was obtained.

Relationship to murine and guinea pig Ia antigens

Genetic and serological studies have demonstrated the following similarities between murine Ia antigens and human *HLA*-linked B-cell alloantigens. (1) There genes are in the MHC and in intimate association with MLC genes[1,31]; (2) Antisera to these products are potent inhibitors of the MLC reaction[6,7,31] and also block generation of plaque-forming cells *in vitro*[32]. And (3), they have similar tissue distributions[1-9,31]. Our report shows that the two-chain, glycoprotein structure of *HLA*-linked B-cell alloantigens seems similar to that of murine and guinea pig Ia antigens[28,31,33]. Moreover, the NH_2-terminal sequence of the guinea pig Ia antigen smaller chain[33] is identical to that of human p29 in three out of seven positions, strongly suggesting inter-species homology. Similarly, sequence studies have shown that *HLA-A* and *HLA-B* antigens are homologous to murine H-2 D and K antigens[34] and to guinea pig GP-LA B antigens[33]. However, murine and guinea-pig Ia antigens analysed after immunoprecipitation have been found on some but not other occasions to contain a disulphide bridge between their subunits[33,35]. Thus, these rodent Ia antigens might also contain free cysteines in each subunit, but would differ from the human analogues studied here in that their sulphydryls can readily form an interchain disulphide link.

It is not yet known whether *HLA*-linked B cell alloantigens resemble murine and guinea pig antigens in a further respect. The latter alloantigens are termed immune associated (Ia) because their genes co-map with (but are not necessarily identical to) immune response (*Ir*) genes[31]. This type of close association has not been established in humans. However, susceptibility to certain diseases, which may reflect the absence of particular *Ir* genes, is linked to the *HLA* region[36].

Ir gene function may be expressed in T cells, B cells, or both[37-39]. Stimulated T cells express Ia antigens, although in lower amounts than B cells[39,40]. It is thus possible, although not yet demonstrated, that Ia antigens may in fact be the products of *Ir* genes. If so, the homologies between the subunits of *HLA*-linked B-cell alloantigens would have implications for its role in the immune system as a human *Ir* gene product. Proteins with homologous subunits (immunoglobulins, haemoglobins, and isozymes are examples) often can be composed of any of a set of interchangeable subunits which are specified by duplicated genes. Since many unique combinations can be made using a much smaller number of unique subunits, great diversity in functional specificity can be generated in an economical fashion.

Water vapour concentrations at the mesopause

MEASUREMENTS of atmospheric water vapour concentrations have been confined to altitudes below about 50 km showing an average volume mixing ratio of about 4×10^{-6} in the middle and upper stratosphere[1]. Only limited and rather indirect observational information on water vapour exists above 50 km including, for example, the presence of hydrated positive and negative ions and noctilucent clouds likely being composed of water ice particles. In a previous attempt to derive water vapour concentrations from measurements of hydrated positive ions, a mixing ratio between 1 and 2×10^{-6} below 78 km and a sharp decrease above was inferred[2]. In this paper, water vapour concentrations are derived at heights between 85 km and 94 km from two rocket-borne mass spectrometer measurements of atmospheric positive ions. The experiments took place at Andoya (69°N, 16°E) on May 31 1972 (ref. 3) and at Kiruna (68°N, 21°E) on August 18 1974 (ref. 4).

The method applied is based on the atmospheric ion reactions

$$NO^+\cdot CO_2 + H_2O \longrightarrow NO^+\cdot H_2O + CO_2 \tag{1}$$

$$O_2{}^+\cdot H_2O + H_2O \longrightarrow H_3O^+\cdot OH + O_2 \tag{2}$$

$$H_3O^+\cdot OH + H_2O \longrightarrow H_3O^+\cdot H_2O + OH \tag{3}$$

The reaction coefficients $k_2 = 1.9\times10^{-9}\ cm^3\ s^{-1}$ (ref. 5) and $k_3 = 3.2\times10^{-9}\ cm^3\ s^{-1}$ (ref. 6) are known from laboratory measurements. They are expected to have no significant temperature dependence. Although no laboratory value exists for k_1, it is reasonable to adopt a value of $1.5\times10^{-9}\ cm^3\ s^{-1}$, as most switching reactions have rate coefficients between 1 and $2\times10^{-9}\ cm^3\ s^{-1}$ (ref. 7). In the conditions considered (high electron densities in excess of $10^5\ cm^{-3}$) the dominating loss process for $NO^+\cdot H_2O$ and $H_3O^+\cdot H_2O$ was electron recombination. The recombination coefficient for $H_3O^+\cdot H_2O$ is $\alpha_2 = 3\times10^{-6}(300/T)^{0.5}\ cm^3\ s^{-1}$, (ref. 8) whereas for $NO^+\cdot H_2O$ an $\alpha_1 = 2\times10^{-6}\ (300/T)^{0.5}\ cm^3\ s^{-1}$ is adopted according to a systematics of α values[9]. Other loss processes for $NO^+\cdot H_2O$ and $H_3O^+\cdot H_2O$ can be neglected, as no ions other than NO^+ and $O_2{}^+$ were found in significant abundances besides $NO^+\cdot CO_2$, $NO^+\cdot H_2O$, and $H_3O^+.\ H_2O$. Processes decomposing $NO^+\cdot H_2O$ to form NO^+, like photodestruction[10] or thermal decomposition, are much slower than electron recombination. Instrumental effects like electric field or shock-induced collisional decomposition of the ions considered, can also be neglected as in these experiments cluster ions of much lower bond energies were measured between 85 km and stratospheric altitudes.

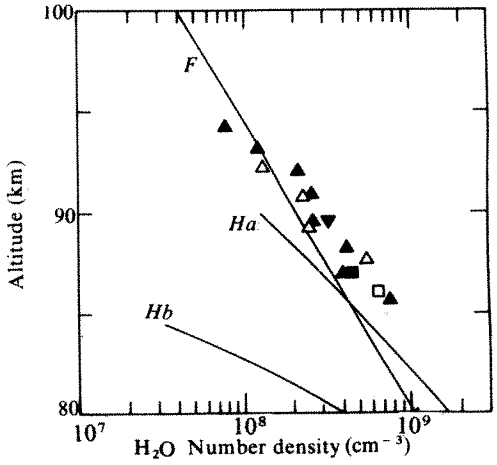
Assuming chemical equilibrium the continuity equations for $NO^+\cdot H_2O$ and $H_2O^+\cdot OH$

$$[NO^+\cdot CO_2]\,k_1\,[H_2O] = [NO^+\cdot H_2O]\,\alpha_1\,[e] \tag{4}$$
$$[O_2{}^+\cdot H_2O]\,k_2\,[H_2O] = [H_3O^+\cdot H_2O]\,\alpha_2\,[e] \tag{5}$$

relate the water vapour number densities to the measured ion densities, the measured electron density, and the reaction and recombination coefficients. Equation (5) neglects electron recombination of the intermediate ion $H_3O^+\cdot OH$ as reaction (3) is much faster. The electron density was measured by wave propagation as well as electrostatic probe experiments[11] with an accuracy better than ±20%. The error of the derived H_2O number densities is mainly introduced by the uncertainty of k_1 and k_2 and by the uncertain temperature dependence of α_1 and α_2. Relative H_2O-densities are not affected by changes in k_1 and k_2 and are only little affected by changes in the temperature dependence of α_1 and α_2 even if a maximum temperature dependence of $T^{-1.5}$ [12] is considered. The latter is true because height variations of atmospheric temperatures in the height range considered are relatively small. Regarding absolute H_2O-densities, an increase by as much as a factor of 2.6 has to be considered if a maximum temperature dependence of α_1, and α_2 of $T^{-1.5}$ is allowed for.

The water vapour number densities derived by use of equations (4) and (5) assuming atmospheric temperatures of the CIRA 1972 model atmospheres are shown in Fig. 1. For each flight both methods gave consistent densities. When compared with each other the H_2O density profiles of both flights agree closely decreasing from $8\times10^8\ cm^{-3}$ at 85 km to $8\times10^7\ cm^{-3}$ at 94 km. The experimental densities are slightly higher than those predicted by photochemical models including strong vertical eddy diffusion (*Ha*[13] and *F*[14]), but considerably higher than theoretical values based on weak vertical diffusion (*Hb*[13]). Using the measured H_2O densities and total gas densities from the CIRA 1972 (ref. 15) model atmosphere for 70° latitude in June and August volume mixing ratios were derived (Fig. 2). They range from 3.5 to 6×10^{-6} for the first and from 3 to 4×10^{-6} for the second experiment. The corresponding average values are 4.5×10^{-6} and 3.5×10^{-6} with no indication for a significant change in the height range 85 km to 94 km. These

Fig. 1 Number densities of water vapour for the experiments F33 (■●) and F36 (□ △) derived by the use of equations (4) (▲ △) and (5) (■ □). Theoretical profiles considering strong (*Ha*[13], *F*[4]) and weak vertical turbulent transport are shown for comparison.



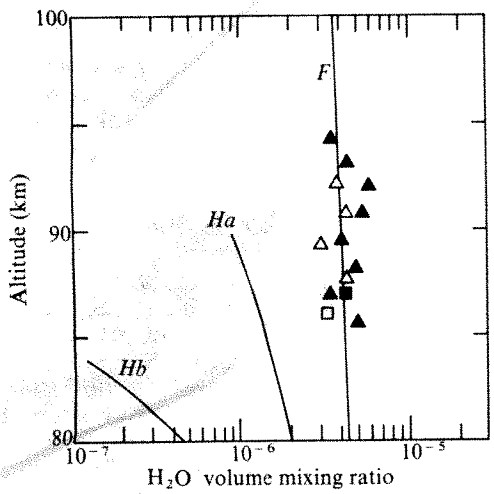


Fig. 2 Water vapour volume mixing ratios (for clarification Fig. 1 caption).

mixing ratios are compatible with the average value of 4×10^{-6} measured in the middle and upper stratosphere[1]. They are also close to a model profile considering strong vertical turbulent transport[14]. It may, therefore, be concluded that strong vertical transport must have been operative when our measurements were made. The transport mechanism may have been either strong turbulent diffusion or a mean upward motion which has been proposed to exist during summer at high latitudes[16]. Further implications from the high H_2O mixing ratios are enhanced hydration of atmospheric ions and enhanced water vapour condensation around nucleation embryos which may be pre-existing solid particles or complex ions. Concerning the ion induced nucleation, a high H_2O mixing ratio is of particular importance as it favours not only the growth of supercritical particles but also the formation of nucleation embryos by subsequent hydration of ions.

Tectonic rotation in Western Canada

THE Queen Charlotte islands of British Columbia form the central part of the Insular Fold Belt, which is the most westerly tectonic unit of the North American Cordillera. In 1971, we collected oriented cores from the islands in an attempt to determine palaeomagnetically their motions relative to the stable craton of North America. A knowledge of these motions is needed before one can understand the origin of the Insular Fold Belt and the Cordillera generally. The localities sampled are difficult to reach, and only a reconnaissance was possible, but these preliminary results indicate that the islands have rotated clockwise since the Eocene.

The oldest rock unit of the Queen Charlotte Islands is the Late Triassic (Karnian) dominantly volcanic Karmutsen Formation[1]. It is overlain by the largely sedimentary Vancouver Group, which is cut by syntectonic foliated batholiths, the Older Plutons. The Older Plutons have K–Ar hornblende ages ranging from 156 to 142 Myr (refs 2–4). The Vancouver Group is unconformably overlain by the dominantly sedimentary rocks of the Long Arm Formation and the Queen Charlotte Island Group. Lying unconformably above these are the volcanics of the Masset Formation which have yielded a K–Ar mica age of 62±Myr (ref. 1) indicating a Palaeocene age. The Masset Formation is cut by the post-tectonic Younger Plutons. The Younger Plutons are massive unfoliated bodies, which have yielded K–Ar biotite and hornblende ages ranging from 39 to 26 Myr (ref. 1). This indicates that they are Oligocene, but the ages may represent the time of uplift and the bodies could have been emplaced in the Palaeocene or Eocene. The Masset is overlain unconformably by Neogene sediments. Samples were obtained from the Karmutsen Formation, the Older and Younger Plutons, and the Masset Formation (Fig 1). No coherent magnetisation was found in the Older Plutons (CP1, 2, 3, 14, 15 and 16, Fig. 1).

The Karmutsen Formation is over 4,000 m in thickness and consists mostly of basalts. It was sampled at four sites on Kunghit Island (CK1 and 2), and in Douglas Inlet (CK3 and 4). Excellent coherence after demagnetisation occurs at three sites. At Kunghit the directions are reversed, and at Douglas Inlet they are normal. The rocks have

Fig. 1 Sampling localities in the Queen Charlotte Islands. (Geology from ref. 1.)

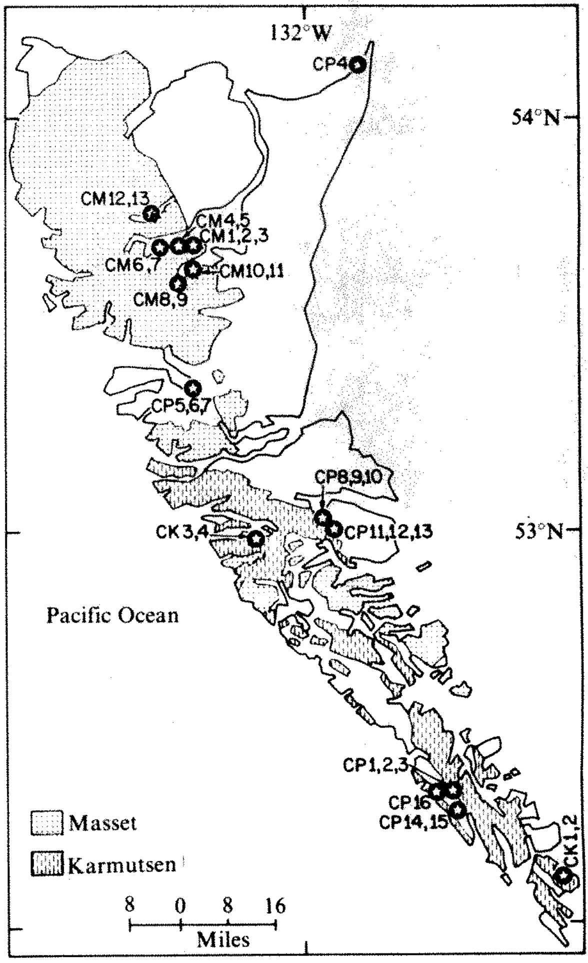

Table 1 Results of samples taken from the Queen Charlotte Islands

	*B**	*N*	Means	*k*	α°_{95}
Masset Formation directions	8	52	026, +78	81	6
Masset Formation poles	8	52	097°W, 72°N	24	11
Younger Plutons directions	5	27	338, +80	138	4
Younger Plutons poles	5	27	154°W, 70°N	90	8
Karmutsen Formation directions	3	17	359, +69	68	15
Karmutsen Formation poles	3	17	165°W, 89°N	28	24

*B is the number of sampling sites, *N* the number of cores (two specimens each), declination (long.) and inclination (lat.) of mean direction (pole) calculated irrespective of sign, *k* is the precision, and α°_{95} the circle of confidence. All specimens were cleaned in alternating fields of 30–40 mT. (Site locations and statistics may be obtained from E. Irving).

been metamorphosed to greenschist or amphibolite facies during the Late Jurassic, and the magnetisation could be of this age.

One Younger Pluton was sampled between 1 and 2 km north of Louise Narrows. The rocks are massive quartz monzonites. They give excellent results. Three sites are reversed, and two are normal. Five cores of Karmutsen basalt from the contact aureole 30 m north of the contact gave general poor overall coherence, but three other cores had reasonable end points with a mean of 345, +51, in rough agreement with directions just inside the pluton (CP11 and 13). It is difficult to estimate the horizontal plane at the time the plutons were magnetised, but there is no reason to suspect that they have been tilted and no correction has been made.

Thirteen sites were sampled from the Masset Formation on Ian Lake and Masset Inlet (Fig. 1). No coherent magnetisations were found in the basalts at sites CM1 to 3 and CM12 and 13. At the remaining sites the basalts and rhyolites yielded excellent results. Four sites have normal polarity and four are reversed. Apparent dips of the lavas vary from 0° to 10° and may be depositional so no correction has been made. The mean apparent dip is 5° to the NNW, and application of a correction would not substantially affect our conclusions.

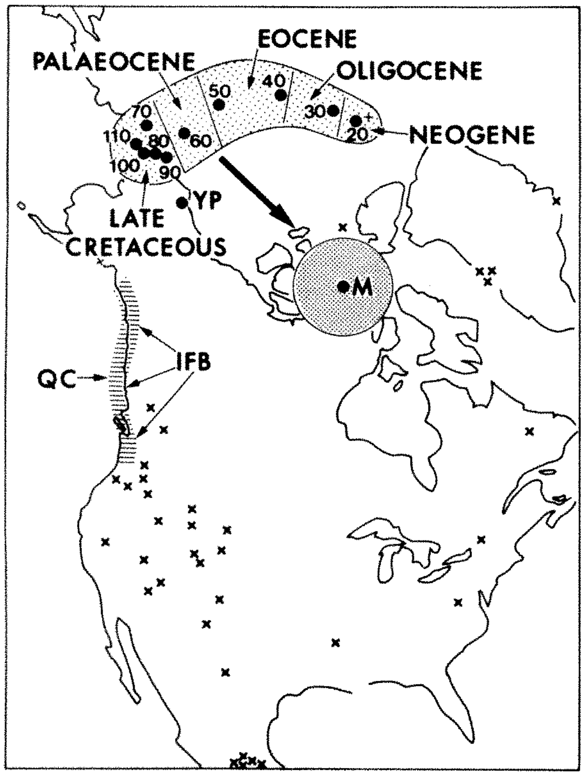

Fig. 2 The pole with its standard error for Masset Formation (M) is compared with the mean polar path for North America. The mean path is based on results obtained from the localities marked X, the results from Greenland being corrected for opening of the Labrador Sea. The mean poles, calculated as overlapping averages for the interval 110 Myr to 5 Myr, are shown, and the zone enclosing them is the envelope of their standard error circles (E. Irving unpublished data.) Standard errors are used because the significance of differences can be readily assessed; if the probable errors do not overlap then the means are significant different at probability of 95%. The present geographical pole is the cross near the Neogene pole, *QC*, Queen Charlotte Islands, *IFB*, Insular Ford Belt, *YP*, pole for the Younger Plutons.

The results are summarised in Table 1. Although the total number of results is not great (16 sites) the precisions are high. The magnetisation of the Masset Formation is considered to be Palaeocene. In Fig. 2 the pole for the Masset Formation is compared with the average pole path for the Cainozoic of a stable North America. The pole is to the SE of its expected position. An anticlockwise rotation of 53±28° brings the pole into conformity with the Palaeocene of North America, suggesting that this part of the Queen Charlotte Islands has rotated at least 25° clockwise since the Palaeocene, indicating that the Insular Fold Belt was originally approximately straight. The pole for the Younger Plutons agrees with the expected Palaeocene position. It is possible that their true age is earliest Tertiary, and that the rotation referred to above may have been completed between the extrusion of the Masset volcanics and the cooling of the Younger Plutons. Only the results from the Masset, however, provide good evidence for rotation, the data from the Younger Plutons being insufficient.

We gratefully acknowledge discussions with Dr A. Sutherland-Brown, and critical comments by J. L. Roy and P. H. Serson.

Frequency dependence of elasticity of rock—test of seismic velocity dispersion

LINEAR theories of attenuation of acoustic or seismic waves in media, such as rocks, which are characterised by constant or nearly constant Q factors (fractional energy loss per cycle equals $2\pi/Q$), imply velocity dispersion and, therefore, frequency dependence of elasticity. The effect is small, corresponding to a change of order 1% over the period range of seismological interest (1 s to 1 h), and is consequently difficult to observe. However, it leads to an internal inconsistency in the development of earth models by inversion of free oscillation data and to discrepancies between these models and body wave data[1-3]. It is a matter of considerable geophysical interest to resolve the problem. Validity of the linearity assumption has been questioned[4] but we are now observing elliptical hysteresis loops in basalt and granite samples subjected to sinusoidal strains of order 10^{-6} and this is strong evidence that attenuation does become a linear phenomenon at low strain amplitudes. But whether or not perfect linearity applies, a direct demonstration of body wave dispersion is the most satisfying indication that earth model studies need revision.

The requirement of causality in linear attenuation theories (which we propose to review in a separate paper) leads to the relationship between phase velocity $v(\omega_0)$ at angular frequency

ω_0 and an integral involving the attenuation coefficient, $\beta(\omega)$

$$\frac{1}{v(\omega_0)} = \frac{1}{c} - \frac{2}{\pi} P \int_0^\infty \frac{\beta(\omega)}{\omega_0^2 - \omega^2} \, d\omega \tag{1}$$

where P indicates the Cauchy principal value of the integral, c is a constant (phase velocity at $\omega \rightarrow \infty$) and a plane wave of any frequency ω decays with distance x as $\exp(-\beta x)$. For the present purpose, it suffices to assume that the behaviour of β at very high frequencies is such that the integral in equation (1) converges but that over a wide range of frequencies about ω_0, β is proportional to ω, which is very nearly equivalent to the constant Q assumption because

$$\beta = \omega / 2Qv \tag{2}$$

the velocity dispersion being slight. Then it follows that, to first order in Q^{-1}, values of elastic modulus μ (real part of the complex modulus), at frequencies ω_1 and ω_2, are related by

$$[\mu(\omega_2) - \mu(\omega_1)]/\mu(\omega_1) = (2/\pi Q) \ln(\omega_2/\omega_1) \tag{3}$$

The derivation of equation (3) demonstrates the equivalence for practical purposes of the alternative empirical linear theories[5-7], which differ only in the assumptions regarding the high frequency behaviour of β, as well as the mechanistic theory based on logarithmic creep[8-11]. The logarithmic dependence of elasticity or velocity on frequency is characteristic of frequency independent Q; other assumptions regarding $\beta(\omega)$ lead to quite different results, so that the direct observations which we report here, confirming the validity of this relationship, also support the constant Q assumption. The logarithmic dependence seems to have been quoted first by Kolsky[12], but we have been unable to find the earlier derivation. This dispersion law also satisfies the observations of pulse shape in acoustic experiments[12,13] and in particular the increase of pulse rise time τ with time of travel and Q for the path[13]

$$\Delta\tau \approx 0.5 \int Q^{-1} \, dt \tag{4}$$

Our experiment is similar in principle to that of McKavanagh and Stacey[14], who measured the mechanical hysteresis of rock cores under cycled axial compressions. Our specimens are tubes of rock of length about 280 mm, diameter 44 mm and wall thickness 5 mm, and are subjected to torsion. The use of thin walled tubes ensures that the strain, which is pure shear, is approximately uniform through the material. The specimen under examination is connected to a standard tube, either of high Q steel or of fused quartz, subjected to the same torque and used to infer the stress. Rings, fixed about 20 mm from both ends of each specimen and standard, are used for mounting capacitance plates, which are centred about 200 mm from the specimens. Relative displacements of the plates record the twist of the specimen between its mounting rings. Balanced sets of plates are mounted on opposite sides of each specimen to minimise effects of asymmetry and thermal drift. Measurements of capacitance are made by means of ratio transformer bridges[14,15] with rapid response times (10^{-3} s) which avoid the appearance of any instrumental phase lag in the measured strains.

Small stresses are applied by means of loudspeaker coils mounted on a lever arm connected to one end of the standard specimen and driven by current from a low frequency sinusoidal oscillator. Strains in the rock specimen and standard are recorded on an X–Y recorder, giving, in effect, a stress–strain plot as the strain is cycled. With the granite and basalt specimens which we have used in this experiment, the hysteresis loop is barely apparent. However, by subtracting the two bridge outputs from one another (specimen minus standard) in a difference amplifier, with independently controlled gains on the two inputs, and further amplifying the difference signal, we can plot directly the departure of specimen strain from linearity with strain of the standard. This appears as a loop of adjustable width, whose area is a measure of the hysteretic loss in the specimen, relative to the standard. The slope of the axis of this loop is a very sensitive indicator of the elastic modulus. The fact that we are able to observe such fine details of loop shape at strain amplitudes as low as 10^{-6} (hopefully lower with improvements now planned) is due to the high sensitivity and wide linear range of the capacitance displacement transducer[14-17].

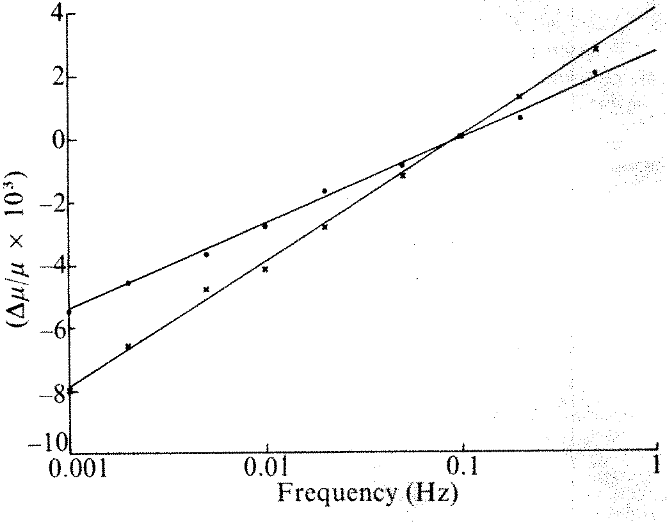

Fig. 1 Frequency dependences of rigidity moduli of basalt and granite specimens over the range 0.001–0.5 Hz relative to values of 0.1 Hz, which was used as a reference frequency in repeated comparisons. ●, Basalt, $Q = 590$, strain amplitude $= 2.6 \times 10^{-6}$. ×, Granite, $Q = 320$, strain amplitude $= 2.9 \times 10^{-6}$. By equation (3) the gradients correspond to Q values of 546 and 371 respectively.

We have plotted hysteresis loops for specimens of basalt and granite and found that the elastic moduli vary with frequency precisely in the manner of equation (3) over the period range 2–1,000 s, which covers much of the seismic frequency band. Figure 1 gives plots of the data, represented as the fractional changes in rigidity modulus relative to the values at 0.1 Hz. The gradients of the two graphs do not agree perfectly with the theoretical values obtained from the measured Q values by equation (3). The discrepancies may arise because the standard specimens were not completely lossless or from frequency dependence of Q, although the measured Q values were independent of frequency within the accuracy of our measurements.

The hysteresis loops of both specimens were of elliptical form, not cusped at the ends, indicating that within the precision of these observations the attenuation mechanism is linear. This was not the case with the sandstone specimen examined by McKavanagh and Stacey[14], even down to strains of 10^{-6}, or with granite and basalt specimens at strains of order 3×10^{-5}. It seems that the strain amplitudes used in the present experiment are at the upper limit of the linear range. Further instrumental improvements are required to examine with the same precision Q and modulus changes at strain amplitudes below 10^{-6}.

If we accept the validity of equation (3) then it should be possible to adjust earth free oscillation data by using measured Q's of the identified modes to remove the effect of frequency dependence of elasticity. Comparison with body wave data also requires recognition of the fact that in the presence of dispersion, as represented by equation (3), the group velocity v_g of a body wave is related to phase velocity by

$$v_g = v(1 + 1/\pi Q) \tag{5}$$

to first order in Q^{-1}. This is the observed velocity in the case of a body wave, but free oscillations effectively measure phase velocity, which for the mantle is of order 0.1% smaller.

Carboniferous unconformity in southern Africa

PALYNOLOGICAL investigations indicate that the Dwyka Tillite of southern Africa is probably entirely of Early Permian age and that the Carboniferous System is absent from this region. Early investigations into continental drift[1] indicated that there were identical late Palaeozoic successions in the southern continents. In this letter, this identity is shown to be incorrect in some respects and, as yet, unsubstantiated in others.

The Dwyka Tillite is most fully developed in the Karoo Basin of South Africa (Fig. 1) although occurrences are known as far north as the equator. The unit reaches thicknesses of up to 1,000 m in a deep sedimentary trough which extends along the southern margin of the basin. There are few reliable palaeontological data for the age of the unit. A small marine invertebrate fauna from South-west Africa was dated as Early Permian[2], and Early Permian miospore assemblages have been reported from Zaïre[3,4], Rhodesia[5], and South-west Africa[6]. A miospore assemblage from above the tillite in the northwestern part of the Karoo Basin was tentatively assigned to the Late Carboniferous[7], but the forms present could equally well support an Early Permian age. There are no reasons to believe that any part of the unit is younger than Early Permian.

Various ages have been reported for the Dwyka Tillite: Early Carboniferous, possibly Late Devonian, to Early Permian[8]; Late Carboniferous[1]; Early Permian[9]. The principal argument for a Carboniferous component for the age rests on an apparent conformable contact in the southern trough between the Dwyka Tillite and the underlying Waaiport Formation of Late Devonian or Early Carboniferous age[8,10]. The Early Permian determinations noted above were all from outside the region of maximum deposition and may represent only later stages.

Within the southern trough, palynomorph microfossils have been badly damaged by heat and tectonism. Three localities (Fig. 1) yielded recognisable specimens. (1) At Elandsvlei, the Dwyka Tillite consists of four sedimentary cycles which can be traced south into the trough and thence eastwards for about 100 km. A sample was taken from the base of the lowest cycle. (2) At Sambokkraal, a deep borehole penetrated 650 m of Dwyka Tillite. A sample of core was taken 1 m above the base of the unit. (3) At Waaipoort, the Dwyka Tillite uncomformably overlies the Kommadagga Subgroup (Fig. 2). A sample was taken from the Miller Diamictite, the lowest unit in the subgroup.

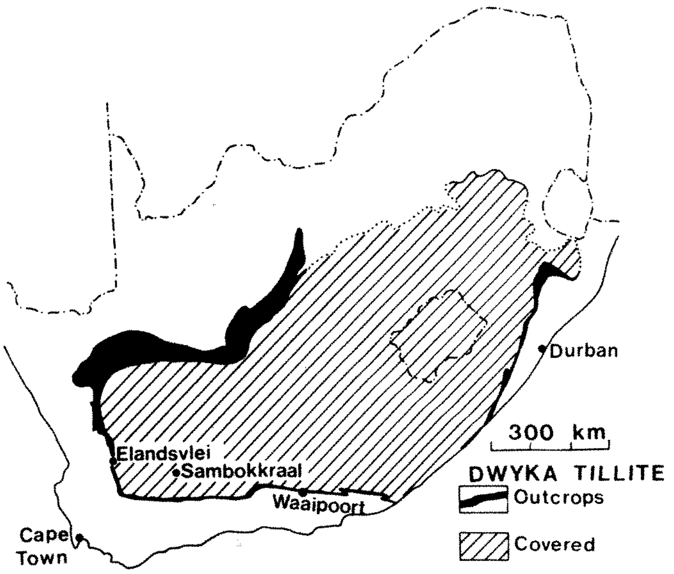

Fig. 1 Distribution of Dwyka Tillite in the Karoo Basin.

The samples should be uncontaminated. The samples from Elandsvlei and Waaipoort were collected from outcrops and the Sambokkraal borehole was cored throughout. The lithologies are too distinctive to be confused with those of any other units in the region. There is insufficient jointing to permit stratigraphic leakage. Normal precautions against contamination were taken in the laboratory.

All of these samples contained bisaccate pollen grains (Fig. 3*a–e*). Although the grains were badly damaged, it was possible to determine that some, at least, had striated central bodies (Fig. 3*a*, *b*, *d*). Many large monosaccate grains were also present (Fig. 3*f*). Early Permian assemblages are characterised by monosaccate and striated bisaccate pollen. The monosaccate grains were too badly preserved to permit identification even to the generic level and similar forms are known from the Late Carboniferous. Striated bisaccate pollen, however, did not appear until well into the Stephanian. Since the sample from the Miller Diamictite was taken 400 m below the Dwyka Tillite, separated from the tillite by an angular unconformity, the base of the tillite is probably above the Permo–Carboniferous boundary. Nevertheless, the possibility exists

Fig. 2 Relationship of Dwyka Tillite to underlying units, southern Karoo Basin.

that Dwyka deposition was initiated in the latest Carboniferous.

At Waaipoort, the Kommadagga Subgroup is underlain by the Waaipoort Formation which, further to the west, directly underlies the Dwyka Tillite itself (Fig. 2). Plant megafossils from the Waaipoort Formation have given ambiguous Devonian or Carboniferous ages. Palaeoniscoid fish, from nodules collected about 200 m below the top of the formation, were dated as Visean on the basis of a broad resemblance at the familial level with Carboniferous fish of Britain[11]. A residue extracted from one of these same nodules contained carbonised Devonian spores including such species as: *Acinosporites acanthomamillatus* Richardson, *Ancyrospora langii* (Taugourdeau–Lanz), *Contagisporites optivus* var. *vorobjevensis* (Chibrikova), and *Dibolisporites echinaceus* (Eisenack) (Fig. 3*g*). Many of the same Devonian species were found reworked into the Miller Diamictite and some Devonian forms were seen in the Dwyka Tillite at Sambokkraal. The assemblage from the Waaipoort Formation indicates a Givetian or possibly Frasnian age. It is unlikely that the 200 m of the Waaiport Formation above the sample horizon would extend completely through the Upper Devonian into the Carboniferous. No other Carboniferous rocks have been reported from subequatorial Africa.

There are insufficient data to permit reliable age determinations for the late Palaeozoic diamictites of Antarctica or the Parana Basin of South America. Those of India and Australia are of Early Permian age, with possibly some Late Carboniferous present in both regions. Thus, the Late Palaeozoic diamictites of India, Australia and southern Africa were all deposited within the same time interval, from latest Carboniferous to Early Permian. This interval is too long, and the ages too imprecise, to determine whether or not the units were actually synchronous.

No Carboniferous is known from Antarctica, though this may be due to incomplete exploration. There is Lower Carboniferous in India and fairly complete Carboniferous successions occur in Australia and South America. Thus, the late Palaeozoic history of Gondwanaland is more complex than has hitherto been indicated.

Some possible acritarchs (Fig. 3*h*) were seen in the Dwyka Tillite at Sambokkraal. No such forms were seen in the Waaipoort Formation and hence they are unlikely to be reworked. It has been postulated that, in the southern trough, the Dwyka Tillite was deposited from a floating ice shelf[10], which might account for the presence of such forms, but such a model is difficult to reconcile with the presence of gymnosperm pollen in the same sample. These samples were diamictite, not interbedded shale. Pollen has been recovered from Dwyka diamictites in other parts of the Karoo Basin and in Rhodesia[5]. In the south-western part of the Karoo Basin, the diamictite has an average organic carbon content of about 0.1%, mostly as terrestrial plant fragments. These data seem incongruent with accepted models of sedimentation for the Dwyka Tillite.

Silicate and the aqueous corrosion of a high-magnesium alloy

Following Butler and Mercer's demonstration[1] that silicate derived from dissolution of glass suppresses the corrosion of mild steel in distilled water at 90 °C, we have compared the results of exposure of Magnox AL 80 (a magnesium alloy containing 0.8% of aluminium) to solutions with and without silicate contamination. This showed that silicate enhanced corrosion in alkaline solution, the effect being greater the higher the temperature. Both magnesium hydroxide and an hydrated magnesium aluminium silicate seem to be formed in the corrosion reaction. During our extensive studies[2] of the aqueous corrosion of Magnox AL 80, care has been taken to store and use alkaline solutions in plastic containers since dissolution of borosilicate apparatus readily causes contamination[3]. A few tests have, however, been conducted with

Table 1 Experimental conditions for corrosion tests on Magnox AL 80 in sodium hydroxide solutions (*p*H 11–12)

Test number	Dissolved silicon concentration (mg kg^{-1})	Temperature (°C)	Test duration (d)
1	100	60	120
2	0	105	0.17
3	130	105	0.25
4	0	121	0.1
5	130	121	0.1 1.0

solutions known to contain silicate and data from these form the basis of our observations.

Corrosion experiments were carried out using specimens with surface areas of a few cm^2 cut from Magnox sheet, degreased, and chemically etched in 2% weight/volume citric acid solution for 5 min. The specimens were immersed in sodium hydroxide solutions (prepared from double distilled water) with *p*H values between 11 and 12. In these solutions magnesium spontaneously forms a passivating film[4]. Conditions of the tests in which the behaviour with and without silicate in solution could be contrasted directly are summarised in Table 1.

In Test 1, specimens were exposed to solution contained in a soft-glass tank, the *p*H of the liquid being maintained above 11 by occasional addition of fresh hydroxide solution. The dissolved silicon content was variable but averaged about 100 mg kg^{-1}. The solution for Test 5 initially contained 130 mg kg^{-1} of silicon produced by etching of the flask in which it was prepared. The same silicon concentration in the form of sodium metasilicate was added to uncontaminated hydroxide for Test 3.

Previous measurements over a range of temperatures enabled the corrosion rate in silicate-free solution at 60 °C to be estimated accurately. Measurements at the higher temperatures were made with Magnox samples in PTFE liners within small stainless steel autoclaves each of which was fitted with a pressure transducer and chromel–alumel thermocouple. Average corrosion rates were calculated from the specimens' weight gains, allowing for corrosion product spalling, and assuming the product to be magnesium hydroxide[2]. Independent checks of the overall metal losses derived from the pressure of gas generated in Tests 2, 3 and 5 gave values close to those estimated gravimetrically.

With silicate-free solution our results were consistent with those of Masterson and Harrison[5] for etched Magnox at 40 °C and with data of Blanchet *et al.*[6] for the magnesium alloy GA3Z1 between 65 and 95 °C. In comparison, our tests suggest that corrosion rates for Magnox are a factor of 3 lower than those quoted by Staesche[7] for a Mg–Mn alloy, although the temperature dependence is very similar. Greenberg and Ruther's experiments[8] on alloy AZ 31 gave rates approximately twice what we might expect for AL 80.

At 60 °C average corrosion rates of Magnox in solutions containing silicate were indistinguishable from those in uncontaminated solutions, while at 105 °C the average rate was twice as great, and at 121 °C four times higher, than in silicate-free solutions after similar periods of exposure. This enhancement factor for silicate solution had doubled at the end of Test 5. These results contrast with a fivefold decrease in the corrosion rate of mild steel in distilled water at 90 °C produced by 4.7 mg kg^{-1} of dissolved silicon as reported by Butler and Mercer[1].

On completion of Test 5 the concentration of dissolved silicon had dropped to 0.1 mg kg^{-1}. The possibility that silicate may have reacted with the Magnox was suggested by results from Test 1. Specimen weight gains during this test were incompatible with the weight losses measured after chemically stripping the corrosion product at the end of the experiment unless a magnesium silicate formed part of the corrosion product.

Energy dispersive X-ray analysis (EDAX) showed silicon on specimens from Test 1, and subsequently both EDAX and α-particle back-scattering analysis[2] proved that some samples from high temperature experiments contained silicon in their corrosion products.

An infrared reflectance spectrum was readily obtained with the specimen from Test 3 (sample *b*) which had a thin (1.8 μm) transparent film on a smooth metal surface. This spectrum was compared with one recorded for a corrosion product formed in silicate-free solution—sample *a* (specimen 4 of ref. 2). Figure 1 shows that absorption bands due to bound water (~3,250 cm^{-1}) and to silicate (at ~1,010 and 650 cm^{-1}) are present in addition to those of magnesium hydroxide. From the wavelengths of these bands it is inferred that a polymeric hydrated silicate had been incorporated into the corrosion film.

The corrosion film on the specimen from Test 5, being 30 times thicker, probably contained much more silicate than the product on sample *b*, but a satisfactory infrared spectrum could not be obtained from it as very little incident radiation was reflected from the rough surface. An X-ray powder diffraction spectrum of the corrosion product from this specimen showed the presence of both magnesium hydroxide and a magnesium aluminium silicate of the chlorite type, rather than a simple magnesium silicate.

These results demonstrate that silicate contamination can enhance the corrosion of Magnox AL 80 in sodium hydroxide solutions above 60 °C. Even at this temperature gravimetric data suggest participation of silicate in the process, and scanning electron microscopy–EDAX indicates

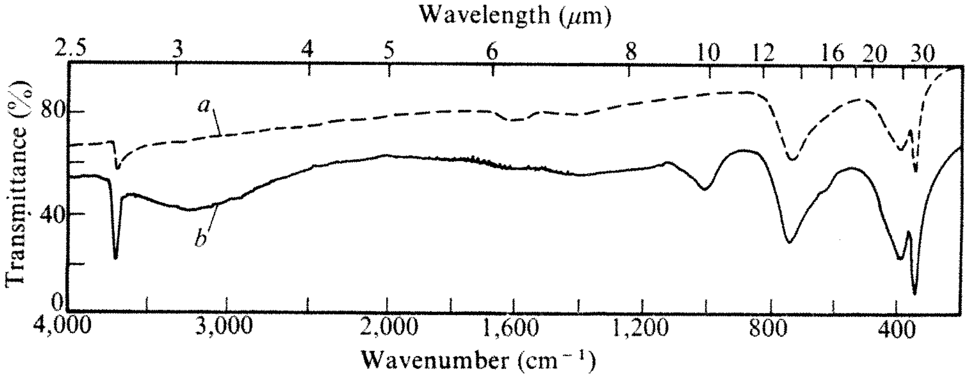

Fig. 1 Infrared reflectance spectra of Magnox specimens coated with thin films of *a*, magnesium hydroxide; *b*, magnesium hydroxide incorporating silicon (Perkin-Elmer 577 grating spectrometer; attenuated air reference).

the preferential formation of a magnesium silicate at grain boundaries. The X-ray diffraction evidence implies that the aluminium content of the alloy, although small, influences the chemical products formed in the corrosion reaction.

It has not been possible here to report on the effect of solution composition on the variation of corrosion rates with time which we have observed, both in experiments involving continuous measurement of gas evolution and by electrochemical techniques. Detailed study of the complex kinetics of the reaction of Magnox with water, its enhancement by silicate and inhibition by fluoride is continuing in our laboratory, and will be reported in due course.

We thank Dr G. C. Allen for communicating his detection of a magnesium silicate by infrared spectroscopy, Dr E. Metcalfe for X-ray analysis of corrosion products and Dr D. A. Hilton for helpful comments. This work is published by permission of the Central Electricity Generating Board.

Thermoluminescence from γ-ray irradiated normal paraffins

IN recent years, an increasing number of papers have described the trapping mechanisms in organic materials including polymers evaluated by thermoluminescence measurement. Several authors have attempted to correlate the phenomena of thermoluminescence glow peaks and the molecular motions in polymers[1,2]. Such studies give useful information on transitional motions which may be responsible for thermal glow from the irradiated organic compounds[3]. This letter presents some of the results obtained from a study of thermoluminescence in normal paraffins above room temperature.

The samples used were commercial normal paraffins in the range *n*-eicosane (C_{20}) to *n*-nonacosane (C_{29}) which were purified by recrystallisation from acetone and/or ethanol hot solution several times. The actual purities estimated from the melting curves were 99.6% for C_{24} and above 99% for the others. All samples were warmed from room temperature to above their melting temperature after irradiation by 0.5 Mrad γ-ray doses, obtained from ^{60}Co at dry ice temperature in air. The luminescence detection apparatus consisted of a photomultiplier (HTV R292) contained in a light-tight box. The temperature was measured by copper–constantan thermocouples attached to the surface of the sample. The calorimetiric measurements were made using a Parkin Elmer DSC II type calorimeter. A scanning speed of 5 °C min^{-1} was employed.

Figure 1 illustrates a typical thermoluminescence glow curve obtained from irradiated C_{24} and C_{28}. Samples were kept in the dark at room temperature after irradiation and during warming. When a sample had given a glow curve, no further light was emitted if it was immediately cooled and reheated. Sharp peaks having very narrow half-line widths of around 0.5 °C were observed in the curves of all the samples, some of which have another broad emission peak on the lower temperature side as shown in Fig. 1. These broad peaks decay relatively fast, while the sharp ones were stable and remained constant in spite of varying with warming rate ranging from 1 to 20 °C min^{-1}.

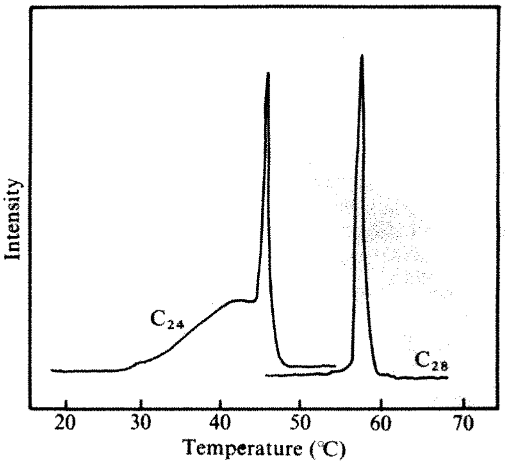

Fig. 1 Thermoluminescence glow curves of irradiated C_{24} and C_{28}. A heating rate of 5 °C min^{-1} was used.

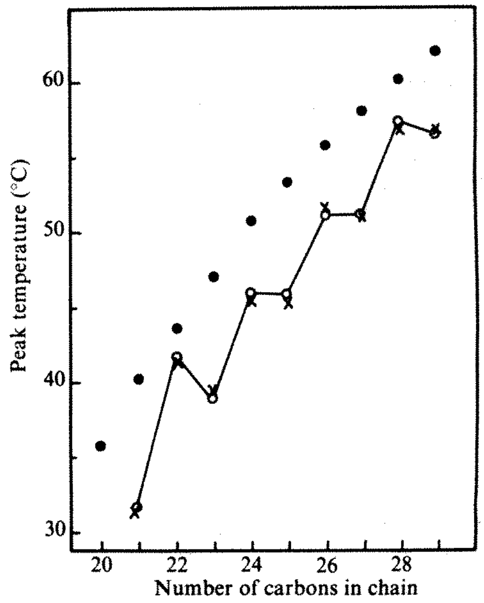
It has been clearly demonstrated that a large number of longer paraffins exhibit first order solid state transitions (see Broadhurst[4]). In general, calorimetric measurements are effective in analysing thermodynamic phase transitions. The glow peaks and DSC peaks obtained are plotted against carbon numbers in Fig. 2. It should be noted here that the glow peaks for all samples were in good agreement with solid state transition points. No significant emission was observed at melting. From these results, thermoluminescence at the transition point is not given by simple Boltzman-type variation with temperature.

Equimolar melts of two paraffins with different carbon numbers were also examined. The DSC curve of such a

Fig. 2 Plot of glow and DSC peak temperature as a function of number of carbons in chain. ×, glow peak; ●, melting point in DSC; ○, transition point in DSC.



mixture has two peaks; one was assigned to the melting and the other, of greater temperature band width was assigned to the solid-state transition in the order of descending temperature. Comparing DSC spectra with thermoluminescence peaks, it is also apparent that for binary mixtures, light emission occurs at the solid-state transition point.

The authors wish to thank Mr M. Ikeda and Dr T. Hatakeyama for calorimetric analyses.

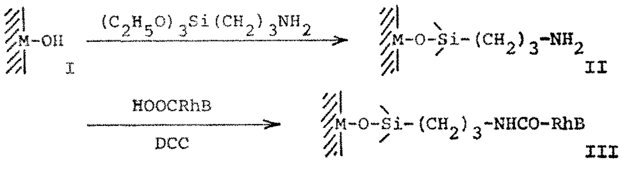
Photocell using covalently-bound dyes on semiconductor surfaces

ONLY TiO_2,[1] SnO_2,[2] and $SrTiO_3$,[3,4] which do not undergo decomposition upon irradiation when used as photoelectrodes in aqueous media, are stable enough to be used as practical solar energy conversion and hydrogen production devices. The band gaps of these *n*-type semiconductors correspond to the energy of photons in the ultraviolet region. Solar energy reaching the Earth's surface has, however, a spectrum distribution in the longer wavelength range and cannot, therefore, be used effectively by these semiconductors[5,6]. Spectral sensitisation would solve this problem by extending the sensitivity of the electrochemical photocells to longer wavelengths. In applying this technique to a real photocell another problem may arise in that most of the solar energy is absorbed by the dye molecules in the solution rather than by the dye molecules adsorbed at the electrode–solution interface, though only the excited adsorbed dye molecules can contribute to sensitisation[7–9]. To cope with this we have developed a new type of photocell[10]. In this, the chemically modified SnO_2 or TiO_2 electrode, with rhodamine B as a sensitiser, was in contact with the transparent electrolyte solution containing a reducing agent as a supersensitiser. In this communication, further developments of this subject are described, especially, the correlation between the efficiency of sensitisation and the structure of the modified layer, which gives us the criteria for more successful chemical modifications of electrode surfaces.

In the previous work, the following surface modification procedure was used to synthesise an amide-linked rhodamine B electrode.



$$\text{M-OH (I)} \xrightarrow{(C_2H_5O)_3Si(CH_2)_3NH_2} \text{M-O-Si-}(CH_2)_3\text{-}NH_2 \text{ (II)} \quad (1)$$

$$\xrightarrow[\text{DCC}]{\text{HOOCRhB}} \text{M-O-Si-}(CH_2)_3\text{-NHCO-RhB (III)} \quad (2)$$

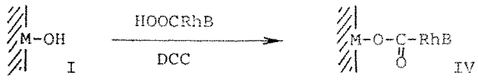
M = Sn or Ti, DCC = dicyclohexylcarbodiimide,

HOOCRhB = rhodamine B

The sensitised photocurrent observed at the amide-linked electrode was less than that observed at the conventional untreated electrode in contact with the dye solution.

Since then, we have tried to increase the surface coverage of the amide-linked rhodamine B (III) and ultimately to increase the sensitised photocurrent by improving yields of the silanisation reaction (I→II). It was found, however, that the observed sensitised photocurrent on the modified electrode (III) decreased, against our expectation, with an increase in the surface coverage of aminopropyl derivative (II)[12]. This led us to assume that rhodamine B covalently bound via amide bond (III) cannot contribute to the spectral sensitisation, and the observed photocurrent on the amide-linked electrode prepared previously can be attributed to rhodamine B directly bound on the surface via ester bond (IV) with the surface hydroxyl group (I) which remains unreacted with γ-aminopropyltriethoxysilane.

Consequently, the following dehydrative coupling of a carboxyl group of rhodamine B with a surface hydroxyl group of the untreated electrode was tried using dicyclohexylcarbodiimide (DCC) as a dehydrating agent[11].



$$\text{M-OH (I)} \xrightarrow[\text{DCC}]{\text{HOOCRhB}} \text{M-O-}\overset{O}{\overset{\|}{C}}\text{-RhB (IV)} \quad (3)$$

As expected, a sensitised photocurrent spectrum was obtained with the ester-linked rhodamine B electrode and was exactly the same as that observed previously on the amide-linked electrode as shown in Fig. 1. Furthermore, the sensitised photocurrent is about two orders of magnitude

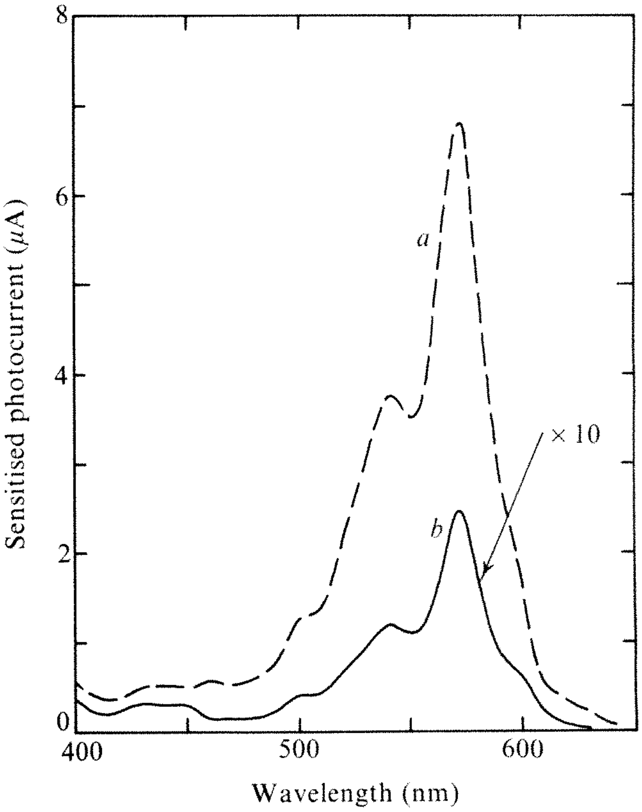


Fig. 1 Spectral dependence of the photocurrent at the chemically modified SnO_2 electrodes with rhodamine B. The cell design used for the photoelectrochemical studies was the same as in the previous paper[10]. The optically transparent electrode was polarised anodically at +0.4 V against a saturated calomel electrode (SCE) and illuminated through the electrode (as shown in Fig. 1 of ref. 10). *a*, Photocurrent spectrum sensitised by a sub-monolayer of ester-linked rhodamine B in contact with a Britton–Robinson buffer (*p*H = 3.9) containing hydroquinone (10^{-2} M) as a supersensitiser. *b*, Photocurrent spectrum observed previously at the amide-linked rhodamine B electrode in contact with aqueous 0.2 M Na_2SO_4 containing hydroquinone (5×10^{-3} M), which is magnified 10 times for comparison.

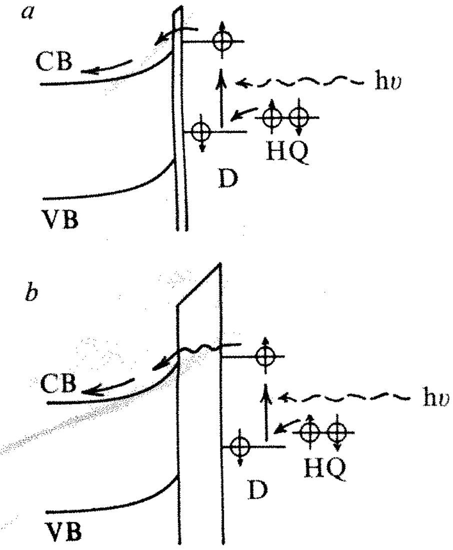

Fig. 2 Schematic presentation of supersensitisation at semiconductor-covalently-bound dye-reductant solution interfaces under anodic bias: D, dye molecule covalently bound on a semiconductor as a sensitiser; HQ, hydroquinone in solution as a supersensitiser; CB, conduction band; VB, valence band. *a*, Ester-linked dye electrode where π electronic system of dye is close to the semiconductor surface. *b*, Amide-linked dye electrode via amino-alkylsilane where π electronic system of dye is apart from the semiconductor surface and a non-conducting alkyl chain intervenes between semiconductor and dye.

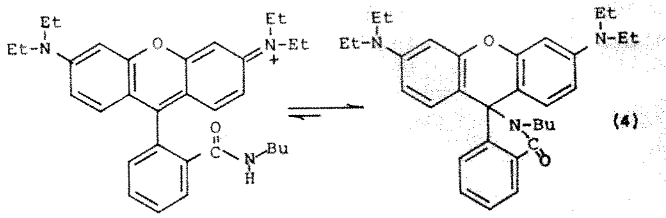
greater on the ester-linked electrode than the photocurrent observed previously on the amide-linked electrode.

The difference in distance of the conjugated π electronic system of rhodamine B from the electrode surface probably accounts for the marked difference in efficiency of the electron injection from excited dye molecules to the conduction band of semiconductor for these ester- and amide-linked electrodes, as shown in Fig. 2. (As these surfaces are chemically predictive, we can evaluate more correctly the height and width of the energy barriers from the properties of binding species such as electron affinity and length of alkyl chains compared with those of the vapour-deposited insulator film such as metal oxides.) In this picture, intervention of the non-conducting alkyl chain in the amide-linked electrode is described as an energy barrier which inhibits the electron injection. This explanation can be supported by the observed difference in electrochemical reactivity of chemisorbed alkenyl hydroquinone on platinum having various lengths of intervening alkyl chain[13] and by the following observation.

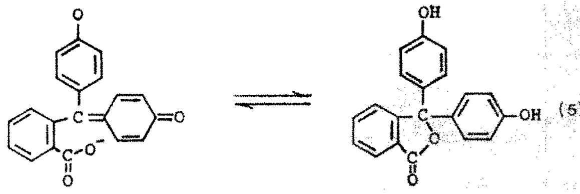
If a monolayer of non-conducting compound at the electrode–solution interface acts as the energy barrier, the electron injection from the dye molecules adsorbed physically at the electrode–dye solution interface should be also inhibited by the presence of such layers. In Fig. 3, a sensitised photocurrent spectrum observed at the aminopropyl modified electrode (II) in contact with the rhodamine B solution is compared with that obtained with the unmodified electrode (I). A pronounced lowering in the sensitised photocurrent was observed by the introduction of nonconducting layers on electrode surfaces.

Parallel to the above experiments, which elucidate why the amide-linked rhodamine B cannot contribute to the spectral sensitisation, the conventional synthesis in solution of the amide and ester derivatives of rhodamine B with butylamine and ethanol was carried out to check the variation of their absorption spectra by derivation. These derivatives were obtained in satisfactory yields by using DCC under the same experimental conditions as used for the surface synthesis. The absorption spectrum of aqueous solution of the ethyl ester is very similar to that of rhodamine B, whereas the butyl amide is surprisingly almost colourless in most solvents. This is because the amide derivative is stable in the lactam form rather than the amide form as shown in equation (4).



(4)

Thus, the deep red colour arising from the quinoid form in the xanthane structure of rhodamine B disappears due to lactam formation of the amide derivative, seen similarly in the acid–base equilibrium of phenolphthalein.



(5)

Because the amide-linked rhodamine B loses colour, an insulator model is unnecessary in this special case to explain the lowering of sensitisation efficiency of amide-linked rhodamine B. It is very important, however, to clarify how the intervening non-conducting layer affects the spectral sensitisation process in view of an important role of lipid membranes in photo-oxidation of water[14,15]. Probably the chemical modification approach as illustrated in this paper is the best method at present to tackle the problem.

In conclusion, if the chemical modification of electrode

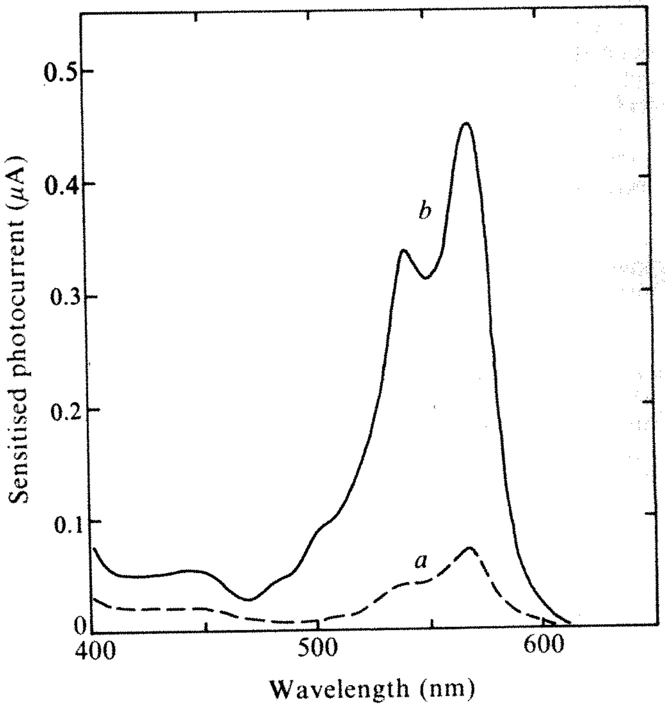


Fig. 3 Spectral dependence of the photocurrent at the electrode–dye solution interface. The conditions for photoelectrochemical measurements were similar to those described in Fig. 1. *a*, Photocurrent spectrum observed at the aminopropyl modified SnO_2 electrode in contact with a rhodamine B solution (5×10^{-5} M rhodamine B+5×10^{-3} M hydroquinone in 0.2 M Na_2SO_4). *b*, Photocurrent spectrum at the conventional unmodified SnO_2 electrode in contact with the same solution as described in *a*.

surfaces are applied to the solar cells, the sensitisers should be bound as close to the electrode surfaces as possible in order to increase the efficiency of spectral sensitisation. Care must be taken as to how the optical properties of sensitisers are changed by the modification reactions.

We thank Professor Kunio Ogasawara for his helpful discussion on synthesis of rhodamine B derivatives.

Spanish rock art depicting honey gathering during the Mesolithic

THE end of the Upper Palaeolithic and the subsequent Mesolithic of western Europe coincided with a general change of climate, flora and fauna. Throughout this time the nomadic hunters and food gatherers continued their former activities and perfected their techniques in a changing environment, before the introduction of agriculture and the change to a sedentary way of life. In Spain, this period is associated with a type of rock art known as 'art of the Spanish Levant', because it occurs only within a limited area of the mountainous coast of eastern Spain; it is provisionally dated approximately from 8,000 to 2,000 BC. Its outstanding features are the appearance of motion and the fact that the central figures are mainly human, around which animal figures are grouped. We report here a scene we discovered last year at one of the most important Levantine rock-art zones, the Barranco de la Valltorta (Castellon), which is a dried out, deep and eroded river bed. It shows wild honey gathering activities and depicts the first definite ladder constructed of side ropes, with visibly rigid intersecting rungs, which are straight and even, and which must be sticks prepared for this purpose.

A stretch of about 7 km of the Valltorta contains 14 rock-art sites, totalling 39 painted rock shelters, located on both banks of the ravine (Fig. 1); these were all discovered in 1917. The paintings of the left bank have been recorded in part and published[1,2,5], while those of the right bank, located on steep cliffs and very difficult to reach, were reputed to contain only meaningless remains of paintings. During a study of the origins and development of Levantine rock art, we have checked and redrawn all known sites. On the right bank we found some paintings which could still be interpreted and correlated because the only damage they had sustained was due to frost and natural erosion. Difficulty of access had protected them from the moistening and rubbing which has defaced so many Levantine rock shelters.

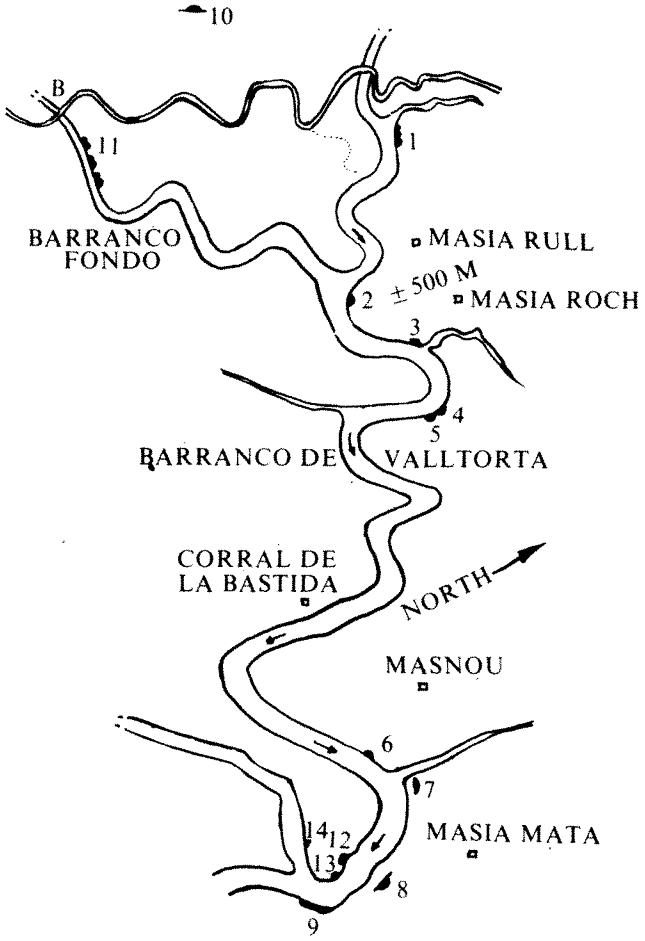

Fig. 1 The Barranco de la Valltorta and its 14 Levantine rock art sites: 1, El Civil; 2, Cueva dels Tolls Alts; 3, Cueva Rull; 4, Els Caballs; 5, Cueva del Arco; 6, Mas d'en Josep; 7, Cueva Alta del Llidoné; 8, Calsaes del Matà; 9, La Saltadora; 10, Coveta de Montegordo; 11, Cingle de la Eremita del Barranc Fondo; 12, Cingle dels Tolls del Puntal; 13, Cueva Grande del Puntal; 14, Covetes del Puntal.

The scene we are reporting is inside rock shelter no. 4, counting from the left, of the Cingle de la Eremita del Barranc Fondo, which is a small subsidiary of the Valltorta. This group of six rock shelters, of total length 96 m, is on the left bank of the narrow Barranc Fondo and can be reached only from the upper plateau. Rock shelter No. 4 contains several paintings in various shades of red, from a faded pinkish red to a reddish Sienna brown. In general the brownish paintings are the oldest. The panel is on the right side of the rear wall and undoubtedly depicts wild honey gathering activities (Fig. 2).

Human figures climbing ropes or ladders can be seen in several Levantine sites, but cannot always be interpreted as evidence for honey gathering. One well known scene is that of La Araña (Valencia) which has been reproduced many times[3]; a lesser known group is that of Dos Aguas (Valencia)[4], and we believe a third to be visible at Los Trepadores (Teruel)[6]. The new honey gathering scene would thus be the fourth.

The rock surface of the rear wall is uneven and shows many small fissures, crevices, and cup-like holes. The faded red colour of the painting indicates a late phase of Levantine art; this is confirmed by the small size of the human figures, as the tendency is for figures to become smaller and more schematic before the disappearance of this type of rock art. Several small cup-like holes at the top were the starting-point of the composition, for they depict the wild bees' nest. The similar scenes of La Araña and Dos Aguas also have a natural hole as a starting point. The total height of the scene, starting from the holes, is 52 cm.

Below the holes, two fissures have been made more conspicuous by outlining with red paint; at the right, the painted lines converge to a central stem evocative of the branch of a tree; on the left, the faded outline of a small animal, which may be a wild goat, can still be traced. Both fissures converge into the rough shape of a V; at this point, there is a squarish object with some appendages radiating out from the corners. This may represent a leather bag or basket for the gathering of honey. The actual ladder begins here and continues downwards for about 40 cm. The bees surrounding the ladder are disproportionately large, but this is also the case in the other honey gathering scenes.

The ladder is of complex construction, being the first of this type to be observed in Levantine rock art; it is a much more sophisticated version of the plain ropes attached to forked sticks at La Araña. At some places, sticks are attached to the side ropes, as can be seen on the segment of ladder trailing on the ground at lower left; at other places, the rope coils in a serpentine pattern. The thickening of the rungs at the point of contact with the ropes may indicate a knot, and the thickening of the side ropes may be a doubling or tripling of the rope at that particular point.

On the ladder, there are five human figures; the first two, at the top, are climbing in a doubled-up posture, grasping the ladder with both hands, and feet; the second figure from the top may be bearded. The third figure from the top seems to be jumping off or falling down; a fourth figure is again climbing up and the fifth, at bottom, is definitely jumping down from the ladder. A vertical fissure runs more or less parallel to the painted ladder.

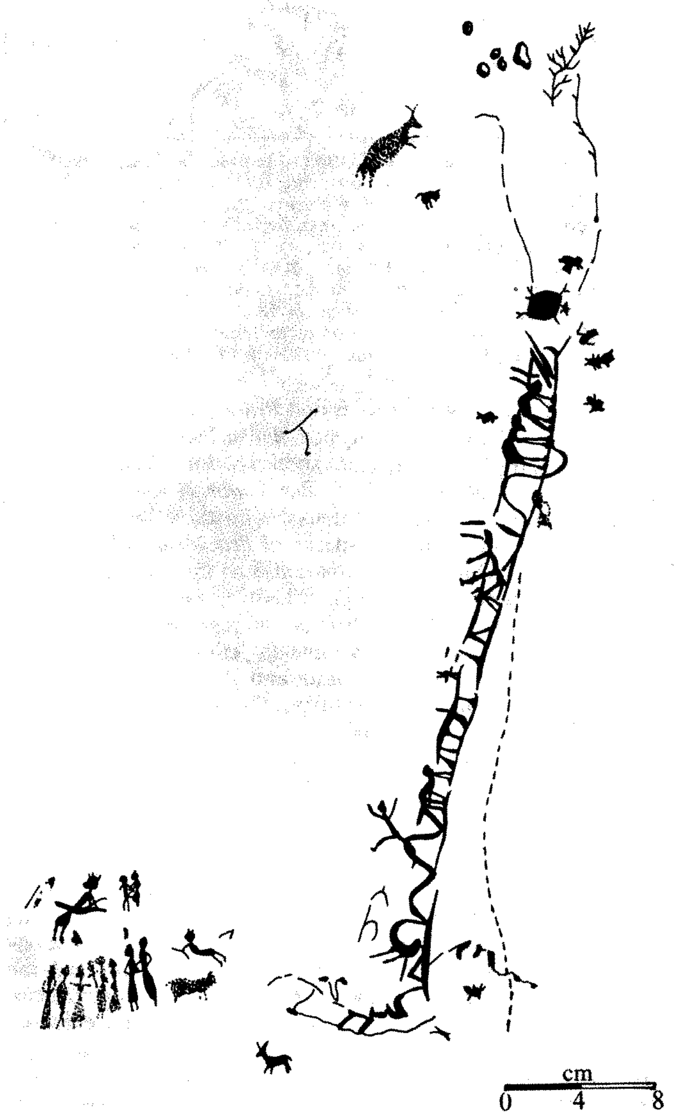

Fig. 2 The honey gathering scene from rock shelter no. 4 of the Cingle de la Eremita del Barranc Fondo.

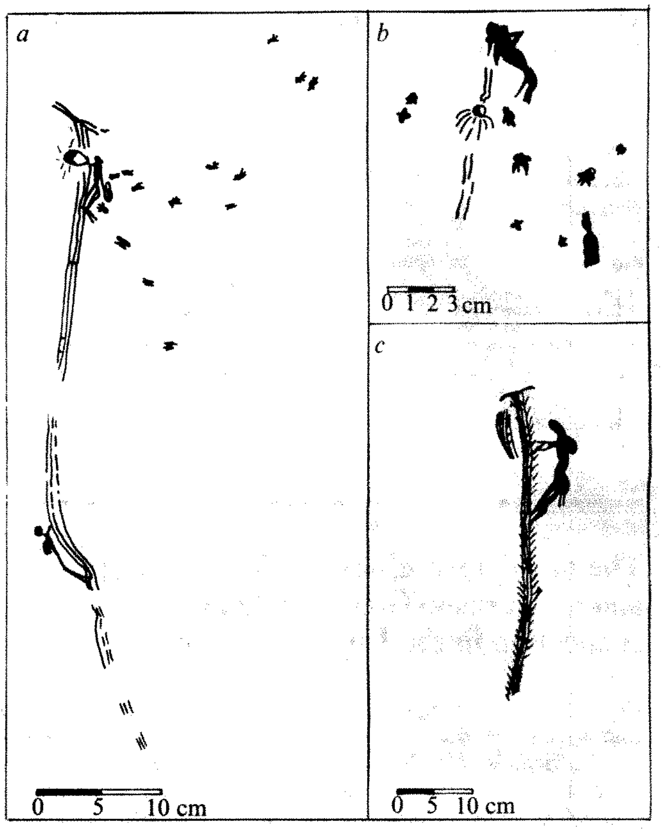

Fig. 3 The honey gathering scenes already known in Levantine rock art: *a*, La Araña; *b*, Dos Aguas; *c*, Los Trepadores.

At the bottom, there are 12 very small human figures, mainly female, a small animal and other remains; two male figures may have bows. The female figures do not seem to be engaged in any particular activity and have no ritual or ceremonial meaning, such as raised arms or dancing postures. This part of the scene is badly damaged by erosion and the small size of the figures (3–5 cm) does not make it easy to connect them with a honey-gathering activity, unless they are supposed to represent onlookers. This scene shows a much more advanced technology than those known from the same periods (Fig. 3), at La Araña (Valencia), Dos Aguas (Valencia) and Los Trepadores (Teruel), and it therefore throws new light on honey-gathering activities during the late Ice Age. Although the use of ropes is depicted in the other scenes, it is not known what type of fibres were involved. But the newly discovered scene shows a ladder built of ropes and wooden rungs, such as are still in use, mainly for mountaineering. The whole construction must have been very strong, as it supports the weight of five people (roughly 300–350 kg); this implies the use of adequately thick and straight sticks of similar weight for the rungs, and firmly tied knots to keep them in place. It would be interesting to know how the top of the whole contraption was attached: it was probably knotted around a projecting rock surface, near the rock fissure containing the wild bees' nest. It is not possible to speculate on the total length of the ladder, for the human figures are probably not drawn to scale.

Honey-gathering scenes are frequently depicted in South African rock art; in one example, at Anchor Shelter, Natal Drakensberg, the ladders are remarkably similar to that shown in the new scene[7,8]. In European rock art, however, the four scenes discussed here are the only indications of this type of activity among Late Stone Age hunters and food gatherers.

The ornithopod dinosaur *Dryosaurus* and a Laurasia–Gondwanaland connection in the Upper Jurassic

COMPARISONS of Upper Jurassic ornithopod dinosaurs show that *Dysalotosaurus lettow-vorbecki* (Tendaguru Beds, Tanzania, East Africa) is referable to the genus *Dryosaurus* (Morrison Formation, western North America). This extended distribution of *Dryosaurus* provides additional evidence for a land connection between Laurasia and Gondwanaland sometime in the Upper Jurassic.

The close similarities of the Upper Jurassic dinosaur faunas of the Morrison Formation of the western United States and the Tendaguru Beds of Tanzania, East Africa (Tables 1, 2) are often cited as evidence for the presence of a Jurassic land connection between Laurasia and Gondwanaland (Fig. 1*a*). As regards genera common to both faunas (Table 1), most authors cite the enormous sauropod *Brachiosaurus*[1-5], and some also mention the smaller sauropod *Barosaurus*[1,2,6,7]. The complete anatomy of the Tendaguru species of *Brachiosaurus* is well known[7,8], but the material of *Barosaurus* is less complete[7]. The referral of the Tendaguru species to these genera is probably correct but as the type species of *Brachiosaurus* and *Barosaurus* from the Morrison Formation is so far each represented by only one partial skeleton described[9,10], the possibility that one or both of the Tendaguru species represent separate but related genera cannot be completely eliminated. The large carnivorous theropods *Allosaurus* and *Ceratosaurus* are represented by complete skeletons from the Morrison Formation, but the Tendaguru material tentatively referred[11] to these genera is extremely fragmentary. The one good skeleton of a medium sized theropod (*Elaphrosaurus*)[11] from the Tendaguru Beds is clearly distinct from the Morrison coelurids *Coelurus* and *Ornitholestes*. The stegosaurs or plated dinosaurs are well represented in both faunas, but *Stegosaurus* and *Kentrosaurus* are distinct and not closely related. The bipedal ornithopods are represented by four taxa from the Morrison Formation: the small fabrosaurid *Nanosaurus agilis*[12]; the hypsilophodontids *Othnielia rex*[13] (Table 1), and *Dryosaurus altus*; and the medium sized iguanodontid *Camptosaurus dispar*. Comparisons of the good material of *Dryosaurus altus* with the excellent material of *Dysalotosaurus lettow-vorbecki* (Fig. 2), the only Tendaguru ornithopod described[14], show that these taxa are congeneric as *Dryosaurus altus* (Marsh) and *Dryosaurus*

Scale lines represent 5 cm (*a*–*d*, *i*–*z*) or 1 cm (*e*–*h*). YPM 1915 is holotype of *Laosaurus altus* Marsh, the type species of *Dryosaurus* Marsh[34]. Specimens shown in *j*, *m*, *o*, *u*, *v* and *x* will be fully described elsewhere[35]. I thank the people indicated for their help while studying the figured specimens in their respective institutions indicated by the following abbreviations: AMNH, American Museum of Natural History, New York (E. S. Gaffney); BMNH, British Museum (Natural History), London (A. J. Charig, C. A. Walker); CM, Carnegie Museum, Pittsburgh (D. S. Berman); DNM, Dinosaur National Monument, Jensen, Utah (T. E. White, J. Adams); HMN, Humboldt Museum fur Naturkunde, East Berlin (W.-D. Heinrich, J. Helms, H. Jaeger); UT Universitat der Tubingen (F. Westphal); YPM, Peabody Museum Yale University, New Haven (J. H. Ostrom).

is slender with a variably developed ventrolateral edge. The femora (Fig. 2*s–w*) possess the same suite of characters: a deep cleft separating the lesser and greater trochanters; the deep depression level with the proximally placed fourth trochanter is set well anteriorly on the shaft; distally the medial edges are squared off, there is an anterior intercondyle groove, and the posterior lateral condyle is thin. In the pes the first metatarsal is rudimentary so there were only three movable toes (Fig. 2*x* and *y*).

Fragmentary evidence indicates the presence of *Dryosaurus* in Europe. A slender tibia (Sedgewick Museum, University of Cambridge specimen number J46889) from the lower Oxford Clay (Middle Jurassic, Middle Callovian) of Fletton near Peterborough, Northamptonshire (Fig. 1*a*) is probably referable to *Dryosaurus*. Femora (Fig. 2*z*) from the Wealden (Lower Cretaceous) of southern England that were tentatively referred[16] to *Dryosaurus* differ from femora of that genus in having a deeper anterior intercondylar groove, the anteromedial margin of which is squared off. A new genus *Valdosaurus* (see Fig. 2*z*) is erected for this material, which probably represents a Cretaceous descendant of *Dryosaurus*.

The presence of the hypsilophodontid dinosaur *Dryosaurus* in the Upper Jurassic (Upper Kimmeridgian, base of Tithonian)[1, 17] of western United States and Tanzania provides important additional evidence for the presence of a land connection between Laurasia and Gondwanaland (Fig. 1) sometime in the Upper Jurassic (Kimmeridgian or possibly Oxfordian). A North America–Europe–Africa route is usually assumed, with the connection located in southwest Europe and northern Africa[1–5] (Fig. 1). Support for this route is provided by the occurrence of *Apatosaurus* and *Brachiosaurus* in the Upper Kimmeridgian of Portugal[18]. But, Jurassic deposits in the critical region (southern Spain and Morocco) are largely marine[1,2,17] and, in addition, it is impossible to restore the coast lines in this area accurately as a result of the complexity of movements of the many small areas involved in the Alpine System orogeny[4, 19]. If a European route was involved then presumably a land bridge emerged from the shallow sea between Europe and North Africa for a brief period or periods in the Upper Jurassic.

Table 2 Comparisons between Morrison and Tendaguru dinosaur faunas

		Genera	Families
Morrison fauna (N or N_2)		18	14
Tendaguru fauna (N or N_1)		11	9
Morrison endemics (E)		9	0
Tendaguru endemics (E)		5	1
Taxa in common (C)		5	7
Simpson's coefficient $(C/N_1)\times 100$		45%	77%
Coefficient of difference $(1-C/N_2)\times 100$		72%	50%
Degree of endemism $(E/N)\times 100$	Morrison	50%	0%
	Tendaguru	45%	9%

No dinosaurs have yet been reported from the Jurassic deposits of Central America or northern South America[6], but the possibility that the Morrison–Tendaguru land connection involved the route North America–South America–Africa (Fig. 1) should not be ignored. The southern end of the South Atlantic opened first but a land route was still present between South America and Africa in the Lower Cretaceous (Aptian)[20]. The Central Atlantic began to open in the early Jurassic[1,19] with the Azores–Gibraltar ridge marking the line of shear between Europe and Africa as the latter separated from North America[1]. Gordon[21] shows a wide connection between the Pacific and the Central Atlantic throughout the Jurassic but his maps, like those in Colbert[5], are based on the reconstructions by Dietz and Holden[22]. In other reconstructions, North and South America are shown much closer together [1, 22-26] and even in contact[27]. Berggren and Hollister[23] consider that there was a marine connection for much of the Jurassic across Central America between the Pacific and the Central Atlantic, but note that this connection may have been intermittent during the Upper Jurassic. On the basis of marine invertebrates, Hallam[28] shows that a direct marine connection was not established until after the uppermost Middle Jurassic (Lower Callovian) and Ager[24] dates the connection as lower Upper Jurassic (Oxfordian)[24]. The maximum extent for Jurassic seas was reached during the Oxfordian and Kimmeridgian, when between a quarter and a third of the total continental area was covered[1]. While much of western Europe and northern Africa was submerged, there were proportionally shorter stretches of shallow sea separating North and South America[1,17,24-26] (Fig. 1) or possibly no sea at all[27].

The presence of *Dryosaurus* and other similarities (Tables 1, 2) in the Morrison and Tendaguru faunas clearly establishes the availability of a land connection between Laurasia and Gondwanaland sometime in the Upper Jurassic (Oxfordian?, Kimmeridgian) or possibly in the uppermost Middle Jurassic (Upper Callovian). But whether this connection was through Central America or western Europe cannot be determined at the moment.

Vesicular–arbuscular mycorrhiza in some aquatic vascular plants

THE occurrence of vesicular–arbuscular (VA) mycorrhiza in flowering plants is a common phenomenon. Harley[1] pointed out that it is easier to list the few plants from which the endophyte is normally absent. It has been stated that aquatic plants are not infected by VA mycorrhiza[1,2].

Read *et al.*[3] found infection levels to be low and often absent in marsh plants and infection in *Cladium* spp. occurred only during dry periods[4]. During an investigation of root hair development in *Littorella uniflora, Lobelia dortmanna,* and *Isoetes lacustris* VA mycorrhiza was discovered in connection with evaluation of root uptake of inorganic carbon and nutrients[5]. Other submerged and a few emergent aquatic plants were also investigated.

Plants with intact root systems were collected in January and March 1977 in four softwater, oligotrophic lakes in central Jutland, Denmark. All samples were taken from 0.3–0.8 m depth to make sure that the plants had not at any time been above water level. The isoetid species were examined for development of root hairs by phase-contrast microscopy. The percentage of VA-infection was estimated by the root-slide technique[3]. Roots of randomly selected plants were cut into 1-cm segments, cleared and stained by the method of Phillips and Hayman[6]. All segments were examined for infection.

An *Endogone* sp. forming VA mycorrhiza was observed in five of the seven species examined (Table 1). Chlamydospores, vesicles and arbuscles were present in January but only vesicles and arbuscles were found in March. Of the isoetid species frequency of infection was highest in *Littorella uniflora* while *Lobelia dortmanna* was less infected. In agreement with earlier observations[1] no mycorrhiza was found in *Isoetes lacustris. Callitriche hamulata* was not infected in January, but intercellular vesicles were present in March. The type of vesicle was different from that observed in the other plant species. *Phragmites communis* and *Eleocharis palustris* were infected but the level of infection was low. At present nothing conclusive can be said about the differences of infection level of the same species in different lakes, but it is known that in terrestrial plants infection is heaviest in infertile soils[3].

Table 1 Percentage VA-infection in aquatic plants from four oligotrophic lakes, March 1977

Species	Kalgaard		Rævsø		Hampen		Almind	
	%	*N*	%	*N*	%	*N*	%	*N*
Littorella uniflora	82	44	22	79	36	76	96	92
Lobelia dortmanna	55	69	30	57			46	74
Isoetes lacustris	0	48	0	60	0	36		
Myriophyllum alterniflorum					0	43		
Callitriche hamulata					54	26		
Phragmites australis					+		+	
Eleocharis palustris					15	27		

N, Number of segments examined; +, infection observed.

Development of root hairs by the isoetid species is shown in Table 2. Root hairs were present in *Isoetes lacustris* but not in *Littorella uniflora* and *Lobelia dortmanna.* The observation by Shannon[7] that *Lobelia dortmanna* has root hairs could not be confirmed. The plants investigated by Shannon were seedlings cultivated in water, however, which may have influenced the development. In contrast our plants were mature and growing submerged in sandy sediments.

Table 2 Development of root hairs in three isoetid species

Species	Kalgaard	Rævsø	Hampen	Almind
Littorella uniflora	—	—	—	—
Lobelia dortmanna	—	—		—
Isoetis lacustris	+	+	+	

+, Root hair development present; —, development absent.

Ionic absorption and especially uptake of phosphorous is enhanced in plants infected by VA mycorrhizal fungi[8–10]. As the roots of aquatic vascular plants also function as organs for ionic absorption[2] the infection of VA mycorrhiza may have great influence on nutrient uptake, especially in *Littorella uniflora* and *Lobelia dortmanna* that are normally growing in sandy sediments poor in nutrients. The advantage of VA to these plants is further enhanced by the fact that the symbiotic system operates more effectively in low nutrient regimes[8]. The heavy infection of *Littorella uniflora* and *Lobelia dortmanna* is in agreement with the suggestion of Baylis[11] that plants with poorly developed root hairs may be obligatory mycotrophs in P-deficient soils. In contrast to *Littorella uniflora* and *Lobelia dortmanna, Myriophyllum alterniflorum* has its greatest absorptive surface in the free water and thus is less dependent on the root system which may explain the absence of mycorrhiza in this species.

Evolution of long-distance alarm calls in Kloss's gibbon

We present evidence here that proximity of close kin is a plausible hypothesis to explain the evolution of long-distance alarm calls in Kloss's gibbon (*Hylobates klossii*). We discovered two alarm calls produced by adults of this monogamous ape that provide good locational cues and are audible for much greater distances than required to signal the immediate family. Our further finding that at least some Kloss's gibbons settle in territories adjacent to their parental families when they mature and establish their own reproductive groups suggests that the adaptive significance of these calls is to warn neighbouring relatives of the presence and location of danger.

Many species of birds and mammals, including primates, emit vocal alarm signals when a potential predator is detected[1,2]. Alarm calls of birds in particular have received much attention because they well illustrate the adaptive significance of signal structure[3] and because they have been interpreted as animal altruism evolved by kin selection[4]. Interpretation of alarm calls relative to kin selection theory, however, has been impaired by the paucity of data on the distribution of related individuals in wild populations. It is confined further by the lack of knowledge on how predators respond to alarm calls of their prey[1]. These difficulties are partially overcome in this study of alarm calls given by Kloss's gibbons.

Kloss's gibbon is strictly endemic to the four Mentawai Islands, 85–145 km off the west coast of Sumatra, Indonesia[5]. This study was conducted in evergreen rain forest on Siberut, the northern-most Mentawai Island, from September 1971 to October 1974, particularly during 387 d at Teitei Peleigei Forest (1°24′S, 99°1′E) where we identified 15 gibbon groups and their territories. Kloss's gibbons live in monogamous families of two to six individuals and defend territories of 7–11 hectares (ref. 5 and R.L.T. in preparation).

Ten kinds of Kloss's gibbon vocalisations have been identified (ref. 6 and Table 1). Two of them, produced by adults of both sexes, are long-distance alarm calls referred to as sirening and alarm trills (Fig. 1). They were audible to us on the ground up to 800 m away (based on marked, tape-measured trails) and indicate specifically the detection of a potential predator. Audibility range of gibbon calls to a man on the ground may be different from that to another gibbon, up in the forest canopy. It also may vary with time of day[7] and local atmospheric conditions (K. Henwood and A. Fabrick, in preparation). Nonetheless, our ground-level determinations are useful to illustrate relative audibility of various calls in the Kloss' gibbon repertoire. They show that the only vocalisations with audibility ranges as great as those of sirening and alarm trills are male and female songs (Table 1), which apparently function in maintenance of territorial organisation among neighbouring groups[8].

We noted 38 bouts of sirening and alarm trills during our study at Tei-tei Peleigei Forest, 21 times from gibbon families disturbed by one of us and 12 times in response to native hunters. Cause in the other five cases was undetermined, although hunters may have been involved. Sirening and alarm trills that we heard during surveys elsewhere in Siberut in 1971 were also in response to human disturbance. Man is the major and perhaps only stimulus eliciting these long-distance alarm calls. This is appropriate since Siberut natives depend heavily on primate flesh for protein, and there are no other predators on Kloss's gibbon except possibly the reticulated python[5]. The hunters, armed only with a palmwood bow and unfletched poisoned arrows, depend on stealth to approach their prey. Despite several hundred years or more of being hunted by Siberut natives, the Kloss's gibbon population is denser than any other hylobatid population known[5].

The repetitive, frequency-modulated syllables of sirening, the rapidly repeated elements in the alarm trill, and the rich harmonic structures of both (Fig. 1), are characteristics which facilitate directional location of a signaller by recipients making binaural comparisons of phase, time and intensity[1,3]. Our own experience at distances to 800 m is that sirening, which normally (>80% of instances) begins before alarm trills, sounds the general alarm that a predator is in a specified area. Subsequent alarm trills pinpoint its location, providing more accurate information about direction and distance. Redundancy of the calls provides recipients ample opportunity to obtain this information: during tape-recorded bouts of four alarm-calling gibbon pairs, sirening occurred at an average rate of once every 95 s per pair and alarm trills once every 19 s per pair. Thus an average bout of 9.4 min (s.d. ± 7.5 min, R = 2–27, N = 21) includes about 30 alarm trills and 6 sirening calls.

Table 1 Estimated audible ranges of adult Kloss's gibbon vocalisations to a man on the ground

	Vocalisation	Context	Estimated audible range (m)
1	Hoo	Detection of langurs, other gibbons, or humans	50–100
2	Howl	Detection of langurs, other gibbons, or humans	100–150
3	Whup	During female song bouts. Occasionally precedes male song, sometimes emitted on detecting humans	400
4	Whistle	Precedes male song; occurs during female song bouts and is occasionally emitted upon detecting humans	50–100
5	Whoo	Precedes female song	400
6	Sirening	Detection of a human	800
7	Alarm trills	Detection of a human	800
8*a*	Male song	Begins spontaneously or on hearing other males singing	500–700
8*b*	Female song	Begins spontaneously, on hearing other females singing or on encountering another female at territorial boundary	800
9	Quivering squeal	Males fighting (emitted by males)	50–100
10	Whistle–howl	Males fighting (emitted by females)	50–100

Note that six of the ten call types may occur when a predator (human) is detected but only sirening and alarm trills are restricted to this context.

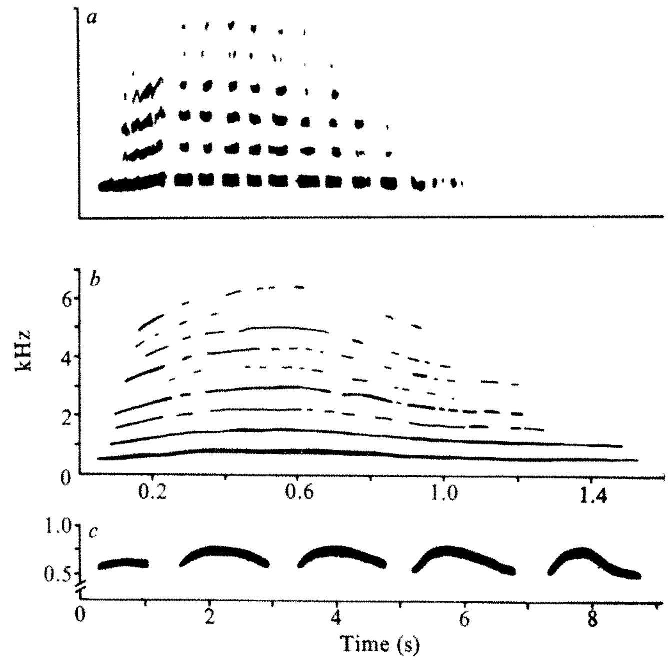

Fig. 1 Ink tracings of audiospectrograms of Kloss's gibbon loud alarm calls. *a*, Alarm trill (time and frequency as in *b*). *b*, One syllable of a sirening call to show harmonic structures. *c*, Example of a complete seven-syllable sirening call (harmonics were deleted in producing the spectrogram, only fundamentals are shown). Mean number of syllables per sirening call is 4.8 (s.d. ± 1.4, R = 3–7, N = 11) and mean duration of the call is 7.8 s (s.d. ± 2.4, R = 5–12, N = 11). Mean duration of the alarm trill is 1.0 s (s.d. ± 0.1, R = 0.93–1.28, N = 21). In 75% (39/52) of cases the alarm trill is preceded by one to three loud 'whups'. Tenaza recorded these vocalisations in the field with a Uher 4400 tape recorder (run at 3 3/4 inches per second) and a Sennheiser 405-S microphone fitted to an aluminium parabola 60 cm in diameter. Audiospectrograms were produced with a Kay Elemetrics sound spectrograph. *a* and *c* were made on wide band setting, *b* on narrow band.

Aboriginal hunters attempting to approach undetected to within bow and arrow range (50 m or less) of Kloss's gibbons usually abandon the effort if the gibbons discover them, although they normally pursue the other primates (*Presbytis potenziani*, *Simias concolor*, and *Macaca pagensis*) in similar circumstances. Hunters give two reasons for this, first alerted gibbons are unusually difficult targets because of their rapid movement in the upper reaches of the canopy, and second, the gibbons' loud alarm calls alert other primates in the vicinity which lowers the hunter's chances of success. We observed all four species of anthropoid primates in Siberut confronting hunters but only the gibbon produced predator-specific alarm calls audible to such great distances. Although the Mentawai langur (*P. potenziani*) emits an alarm call audible to about 500 m, it is given when confronting conspecifics and gibbons as well as when encountering humans[9].

Apparently because a Kloss's gibbon does not further endanger itself by revealing its position to the predator (human hunters), signals that not only announce the presence of danger but also inform recipients of its precise location have been allowed to evolve. If hunters were more capable of capturing alerted gibbons, selection might have resulted instead in alarm calls that are difficult to locate, like the ventriloquial whistles certain passerines and rodents emit when a predator such as a flying raptor is detected[3,10,11].

Sirening and alarm trills may have evolved simply to warn mates and offspring. But, members of a Kloss's gibbon family rarely are more than 10 m apart[5], whereas sirening and alarm trills are audible for about 800 m, more than twice the diameter of an average territory (x diameter = 350 m). Since softer alarm calls in the Kloss's gibbon vocal repertoire (Table 1) are sufficient to signal the immediate family, we suggest their loud alarm calls evolved by selection favouring gibbons who warn neighbours of danger.

Evidence on gibbon genealogy indicates a high probability that gibbons occupying neighbouring territories are close relatives. Four instances of settling by Kloss's gibbons in Siberut were observed. In 1972 a male was apparently being aided by his parents to establish a territory contiguous with theirs, and a female consorted[5] and finally mated (R.L.T., in preparation) with a male holding a territory contiguous to that of her parents. Two additional cases of settling were documented in 1973–74. In one a male was aided by his parents to establish a territory situated 150 m from theirs, and in another a female was accompanied by her parents while being courted by a male whom she eventually settled with in a territory contiguous with that of her parents (R.L.T., in preparation). In each of the three cases where a successful breeding pair was formed, at least one of the pair was the offspring of the occupants of an adjacent or nearby territory. While spatial limitations and the presence of floating males in the population[5] indicate that not all gibbons settle within audible range of their parental families, these observations show that at least some do. In the only other case of settling by a wild gibbon which has been observed, Aldrich-Blake and Chivers[12] report that a male siamang (*H. syndactylus*) established a territory contiguous with that of his parents on reaching physical maturity. Although siamangs do not have specialised long-distance alarm calls, they do emit a distinguishable rendition of their loud territorial call when alarmed by a potential predator[13].

In each case cited above a mature offspring settled within audible range (for long-distance alarm calls) of parents and younger siblings, with each of whom it shares a coefficient of relationship of 0.5. Theoretically, in such a socio-genealogical framework, long-distance alarm calls that do not appreciably lower the individual fitness of a signaller could increase the inclusive fitness of neighbouring relatives and thus be favoured by kin selection[4,14,15]. The fact that every species of gibbon which has been studied produces some kind of distinguishable long-distance alarm call[16–18] suggests this could be true for all species of hylobatids. The apparently high probability of close genetic relatedness among neighbouring Kloss's gibbons makes it unnecessary, in our opinion, to invoke hypotheses of reciprocal altruism[19] or selfish manipulation[20,21] in attempts to explain the evolution of alarm calls in this species.

Role of sister chromatid exchanges in chromatid aberration formation

MECHANISMS of formation of chromatid aberrations are not fully understood. The involvement of chromosome breakage and reunion[1] or exchange[2] has been suggested. DNA repair is a possible cause of aberrations and exchanges[3–5], but a causal relationship between the two phenomena is not clear[6,7]. It is not known whether chromatid deletions derive from unrepaired chromatid breaks or from incomplete exchanges between sister chromatids. The origin of chromatid deletions can be studied by examining whether or not they occur just at the points of sister chromatid exchanges (SCE) (ref. 6). Differential labelling of sister chromatids with 5-bromodeoxyuridine (BUdR) has shown that X-ray-induced chromatid deletions are only infrequently associated with SCE, indicating that most chromatid deletions are not incomplete SCE but simple chromatid breakage[8]. On the other hand, the parallel distribution of SCE and chromosome aberrations induced by two different hydrocarbon carcinogens, 7,12-dimethylbenz (*a*) anthracene and 7,8,12-trimethylbenz (*a*) anthracene has been reported, suggesting that aberrations are incomplete SCE (ref. 9). The results presented here indicate that almost no chromatid deletions or gaps induced by irradiation of BUdR-substituted chromosomes with visible light represent incomplete SCE.

When Chinese hamster ovary (CHO) cells cultured for two rounds of replication in the presence of BUdR were

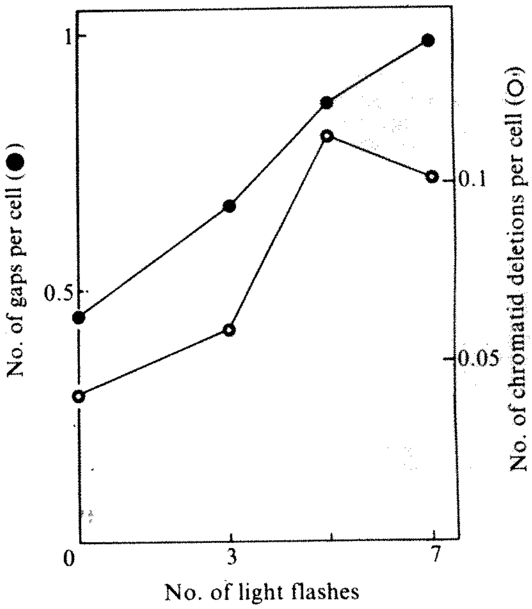

Fig. 1 Frequencies of chromatid deletions and gaps plotted against the number of light flashes. CHO cells were cultured in the dark in McCoy's 5A medium containing 15% foetal calf serum and 10 μM BUdR for 24 h. The cells were then exposed to visible light from an electric photographic flash unit placed 10 cm from the cell layer: the light was filtered through a 5-mm acryl–resin plate. Colcemid (final concentration 10^{-7} M) was added to the culture 2 h before collecting the metaphase cells. The sample was therefore irradiated with visible light in the G_2 phase. Chromosome specimens were prepared and the slides were stained by the Giemsa[12,13] or modified 33258 Hoechst–Giemsa methods[14]. 100 cells were observed for each light intensity.

exposed to visible light from a photographic electric flash unit, chromatid aberrations, excluding exchange types, and SCE, were induced frequently. Using such cells, we investigated whether or not chromatid deletions occurred just at the points of SCE.

The frequencies of chromatid deletions and gaps increased with increasing light flashes, or intensity of visible light (Fig. 1). The number of SCE in each chromosome was also in proportion to the light intensity and the relative size of chromosomes (Fig. 2) (ref. 12). Chromatid aberrations and SCE observed may have resulted from DNA strand breaks induced by photolysis of BUdR-containing chromosomes, for photolysis of BUdR-incorporated DNA leads to polynucleotide strand breaks[10].

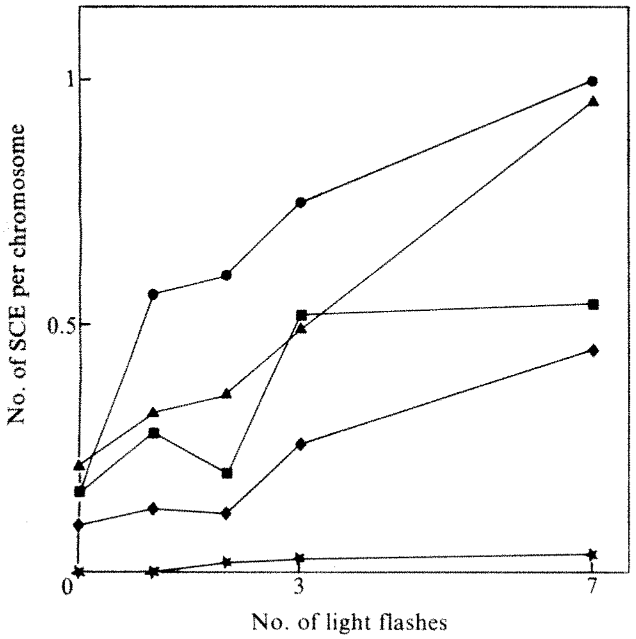

Fig. 2 Frequency of SCE plotted against the number of light flashes. SCE were scored for the largest (●), the second largest (▲), the third largest (■), medium-sized (◆) and small (★) chromosomes, respectively. Each data point represents the analysis in more than 25 chromosomes.

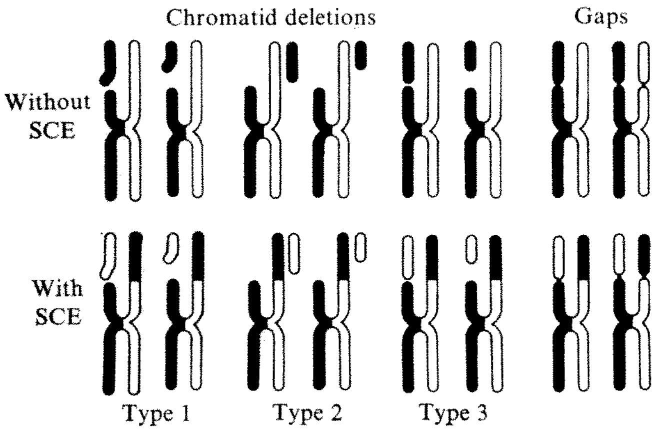

Fig. 3 Schematic representation of three types of chromatid deletions and gaps scored. Type 1, slightly displaced distal segment; type 2, completely displaced distal segment; type 3, nondisplaced distal segment.

Table 1 Chromatid deletions and gaps with or without SCE at breakpoints

Chromatid type*	Chromatid deletions†								Gaps	
	Type 1		Type 2		Type 3		Total			
	+	−	+	−	+	−	+	−	+	−
BB	0	1	0	4	1	24	1	29	22	440
BT		1		2		9		12		170
Total	0	2	0	6	1	33	1	41	22	610

+, With SCE; −, without SCE.
* BB, BUdR bifilarly substituted; BT, BUdR unifilarly substituted.
† Classified according to Fig. 3.

Chromatid aberrations were scored according to whether aberrations were accompanied by SCE. Chromatid deletions were classified into three types according to the position of distal segments (Fig. 3). Only one out of 42 chromatid deletions and 22 out of 632 gaps observed contained SCE at the breakpoints (Table 1). These results indicate that very few chromatid deletions or gaps are incomplete exchanges. This is consistent with the observations for X-ray-induced chromatid deletions[8]. The lesions and/or subsequent processes leading to chromosome aberrations might be different from those involved in sister chromatid exchanges.

Table 1 also implies that bifilarly BUdR-substituted chromatids are more than twice as sensitive to light flashes as are unifilarly substituted chromatids. Equal sensitivity has been found to X rays in unifilarly- and bifilarly-substituted chromosomes, both of which are more sensitive than unsubstituted chromosomes[8,11]. This apparent difference in sensitivity might reflect some fundamental distinctions between the two types of radiation for production and repair processes of DNA strand breaks responsible for aberrations in BUdR-containing chromosomes, although it is difficult to speculate on the nature of the distinction.

The results presented here indicate that, whatever the mechanisms of formation of chromatid aberrations or SCE, the relationship of SCE to chromatid breaks depends on the type of agent used to damage the chromosomes.

Interferon suppresses the transition of quiescent 3T3 cells to a growing state

PAUCKER, Cantell and Henle reported that crude mouse interferon preparations depressed multiplication of suspended L cells[1]. Since then evidence has accumulated indicating that interferon molecules which inhibit multiplication of virus also inhibit the growth of cells in culture[2–9]. Interferon was shown to suppress incorporation of ^{3}H-thymidine into cellular DNA in various systems—for example, release from a double thymidine block in synchronised L 929 cells[10]; activation of mouse spleen lymphocytes by phytohaemagglutinin (PHA) or allogeneic lymphocytes[11]; and in steady-state growth of cultured mouse leukaemia L 1210 cells[12] in a chemostat. However, there has been no direct evidence to distinguish between the effect of interferon on the rate of initiation of DNA synthesis (entry into the S phase) and that on the rate of DNA synthesis in the S phase, and it is uncertain which step of the cell cycle is interfered by interferon. It is well known that most cells in cultures of confluent or serum starved mouse 3T3 stay in the early G_1 or G_0 stage of the cell cycle, and an addition of serum to these quiescent cells stimulates their growth, leading to DNA synthesis and cell division[13,14]. We describe here a suppressive effect of interferon on the transition from the quiescent to the growing state in BALB/c 3T3 cells. The data indicate that interferon suppresses the initiation of DNA synthesis.

Interferon preparations used were obtained from the supernatant of monolayer culture of mouse L cells inoculated with Newcastle disease virus and purified by column chromatography using DEAE–Sephadex and CM-Sephadex (2×10^7 units per mg protein) (ref. 15). Interferon titres were expressed in international mouse reference units.

Confluent and serum-starved quiescent BALB/c 3T3 cells were transferred to fresh medium containing 10% foetal bovine serum and ^{3}H-thymidine with or without interferon, and the proportion of cells with labelled nuclei (labelling index) was determined as a function of incubation time by autoradiography (Fig. 1*a*). The labelling index shows the proportion of cells which have entered the S phase. The cells synthesising DNA began to appear after a 12-h lag period either in the presence or absence of interferon, but the rate of increase of the DNA-synthesising cells was reduced when interferon was present in the culture; that is, interferon reduced the frequency of the initiation of DNA synthesis, but it did not shift the point where cells began to enter into the S phase. The result is reminiscent of the fact that, although serum concentration determines the rate at which cells enter the S phase, the length of the lag period is independent of the serum concentration[17].

Smith and Martin have proposed a new theory on the cell cycle, in which a cell's life is divided into two fundamentally different parts: A-state and B-phase[18]. The B-phase is a determinate one including the S, G_2 and M phases in addition to a part of the G_1 phase. On the other hand, the A-state is rather indeterminate. After mitosis the cell enters the A-state and remains for any length of time with a constant probability of leaving this state ('transition probability'). Brooks has analysed the regulation of the fibroblast cell cycle by serum according to the above theory, and showed that serum factors control the rate of transition from the A-state to the B-phase[17,19].

Figure 1*b* replotted from Fig. 1*a* shows the proportion of cells remaining in the G_1 phase (cells unlabelled) indicating that after 12-h lag period the rate of decrease of the G_1 cells either in the presence or absence of interferon followed first-order kinetics. In this experiment the transition rate constant was 0.13 h^{-1} in interferon-free control cultures, while in those with added interferon (1×10^4 units per ml) it was 0.036 h^{-1}. The rate constant estimated here is not exactly the same as 'transition probability' (P) defined by Smith and Martin[18], since in our experiments a small portion of the quiescent 3T3 cells was not in the G_0 or G_1 phase (A-state). It is closely related to P, however, because the rate of decrease of unlabelled cells after a lag period followed first-order kinetics. Thus, it can be said that interferon reduced the 'transition probability' from the A-state to the B-phase. Furthermore, the transition rate constant declined proportionally to the amount of interferon added (Fig. 2).

The effect of interferon on the transition from the G_1 phase to the S phase was examined when interferon was added at various times following serum stimulation (Fig. 3). When added at zero time or 4 h, the suppressive effect of interferon on the transition was almost the same, but after 4 h it declined, and at the time when the cells began to enter into the S phase the addition of interferon did not show any effect on the initiation of DNA synthesis. A certain period may be required for the expression of the suppressive activity of interferon, or interferon may not have any effect on the cells already committed to DNA synthesis.

Although our interferon preparations are not completely pure, the following results strongly indicate that interferon itself is responsible for the observed effect. First, when the interferon preparations were heated at 100 °C, their antiviral

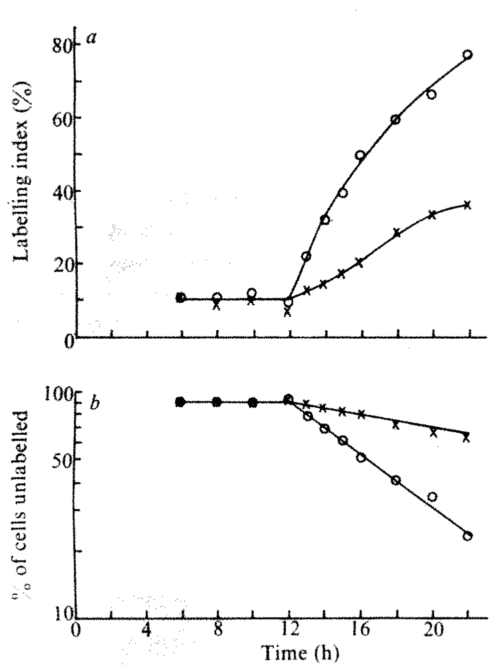

Fig. 1 Effect of interferon on the entry into the S phase after stimulation of quiescent BALB/c 3T3 cells with addition of fresh medium containing 10% serum. BALB/c 3T3 cells[16] (from Flow Laboratories) were plated at 4×10^4 cells on to 15-mm plastic coverslips (Wako Pure Chemical Industries) submerged in each well of Linbro multi-dish tray (Linbro 24-16-TC) containing 1 ml of Dulbecco's Modified Eagle's Medium (GIBCO) with 10% foetal bovine serum (Microbiological Associates), and grown at 37 °C in a 10% CO_2 atmosphere (v/v) until confluent. Four days after they were seeded, cell monolayers ($\sim 2 \times 10^5$ cells per plate) were washed with phosphate-buffered saline, and added 0.5 ml of serum-free Modified Eagle's Medium. After incubation for further 12 h, the medium was discarded and replaced by 0.5 ml of fresh medium containing 10% foetal bovine serum and ^{3}H-thymidine (1 μCi ml^{-1}; 2 μM thymidine) with or without addition of interferon (1×10^4 units per ml). At the times indicated, coverslips were removed and cells were washed with phosphate-buffered saline and extracted with 5% perchloric acid, rinsed with ethanol and air dried. Coverslips were mounted on to glass microscope slides and they were dipped into SAKURA autoradiographic emulsion NR-M2 (diluted with an equal volume of distilled water). After exposure for 7 d at 4 °C, autoradiographs were developed, stained with Giemsa solution, and the proportion of cells with labelled nuclei was determined. *a*, Proportion of cells entering into the S phase (labelling index). *b*, Proportion of cells remaining in the G_1 phase (100 minus labelling index). ○, No interferon; ×, Interferon added.

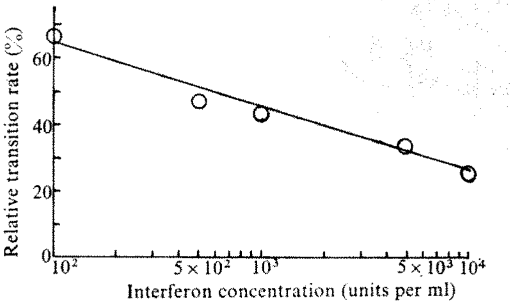

Fig. 2 Relative transition rate as a function of interferon dose. Quiescent and serum starved BALB/c 3T3 cells were stimulated by the addition of fresh medium containing 10% foetal bovine serum as described in Fig. 1. Various doses of interferon were added at zero time. Coverslips were removed at 8, 10, 12, 14, 16, 18, 21 and 24 h, respectively, and processed by autoradiography. Autoradiographs were exposed for 12 d. The proportion of cells remaining in the G_1 phase was plotted semilogarithmically as a function of time and the transition rate constant was obtained. In interferon-free control cultures it was 0.10 h^{-1}. Ordinate indicates the relative transition rate to the control.

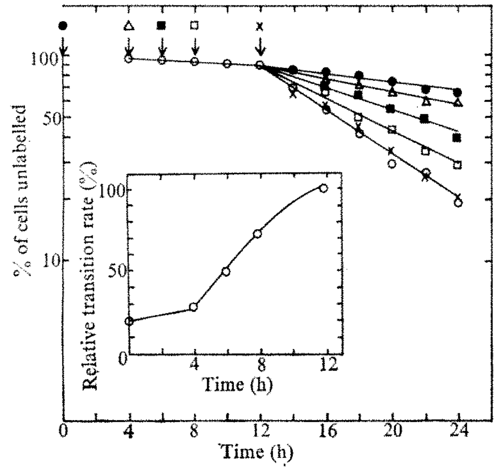

Fig. 3 Effect of addition of interferon at various times during stimulation on the rate of entry into the S phase. Quiescent and serum-starved BALB/c 3T3 cells were stimulated by the addition of fresh medium containing 10% foetal bovine serum, and interferon (1×10^4 units per ml) was added at the times indicated. Coverslips were removed and processed by autoradiography. Autoradiographs were exposed for 7 d. The inset to the figure describes the relative transition rate as a function of the time when interferon was added. In interferon-free control cultures the transition rate constant was 0.13 h^{-1}.

activity was reduced to less than 1%, but on heating in the presence of sodium dodecyl sulphate (SDS), about one-third of it survived (Table 1). The suppressive effect of interferon on the transition from the quiescent to the growing state of the cells was also lost by heating, but preserved if heated in the presence of SDS, in parallel to the antiviral activity (see the dose–response curve in Fig. 2). Similar results have already been reported by Stewart *et al.*[9]. Second, both activities were lost on trypsin digestion of the interferon preparations (Table 1). Third, the L cell interferon preparations, used at 1×10^4 units per ml, did not exert any effect on the serum activation of the serum-starved quiescent BHK cells (data not shown), conforming to the well-known species specificity of interferon action.

Interferon molecules may suppress certain cellular events in the G_1 stage of the cells, since the values for the transition rate constant ('transition probability') reflect the cellular activities during the transition from a quiescent to a growing state (G_1 phase or A-state)[19,20]. The transition is known to be accompanied with a complex set of cellular changes (see ref. 21), termed the "pleiotypic control" by Hershko *et al.*[22]. It was reported that interferon elevates the cellular levels of cyclic AMP in the cultures of L 929 cells[23]. The suppressive effect of interferon on the initiation of DNA synthesis may be resulted partly from the failure in falling of cyclic AMP levels. We have recently observed the effect of interferon on the growth rate, labelling index, fraction of labelled mitosis and mitotic index of BALB/c 3T3 cells in exponentially growing culture. The data showed that the duration of the G_1 phase was only affected by the addition of interferon (in preparation).

Table 1 Antiviral and anticellular activities of interferon after heating with or without SDS, and trypsin digestion

Treatment of interferon*	Antiviral activity† survival (%)	Anticellular activity‡	
		Transition rate constant (h^{-1})	Relative transition rate (%)
No treatment	100	0.015	20
−SDS, 100 °C, 1 min	0.5	0.038	51
+SDS, 100 °C, 1 min	34	0.013	18
−SDS, 100 °C, 4 min	0.1	0.043	58
+SDS, 100 °C, 4 min	34	0.013	18
+Trypsin, 37 °C, 30 min	0.04	0.051	69
Without interferon	—	0.074	100

*Small tubes containing 20 µl of L cell interferon (1×10^7 units ml^{-1}, 0.5 mg protein ml^{-1}) in phosphate-buffered saline were prepared. They were constituted to contain 1% SDS–0.1 mM dithiothreitol or 0.1% trypsin (Sigma) when indicated. After treatment, 80 µl of Dulbecco's Modified Eagle's Medium containing 10% foetal bovine serum was added.

†Antiviral activity was assayed by the method described by Suzuki *et al.*[24]. Reduction of incorporation of ^3H-uridine into RNA of vesicular stomatitis virus in actinomycin-D-treated mouse L cells was estimated.

‡Effect of interferon on the transition from a quiescent to a growing state in BALB/c 3T3 cells was observed as described in Fig. 1. Non-treated interferon was used at 5×10^4 units per ml.

Inhibition of lymphocyte-induced angiogenesis by isolated chondrocytes

LYMPHOCYTE-induced angiogenesis (LIA) has been introduced by Sidky and Auerbach[1] as a quantitative and sensitive assay for measuring cell-mediated immunity *in vivo*. In this assay immunocompetent lymphocytes are injected intradermally into allogeneic or semiallogeneic mice. A local graft versus host (GVH) reaction is therefore induced, resulting in new blood vessel formation. As early as the second day post-injection, this effect could be observed in a dose–response fashion dependent on the number of cells injected. The relationship of lymphocyte-induced angiogenesis to tumour-induced angiogenesis mediated by tumour-angiogenesis factor (TAF)[2] remains theoretical. Folkman and others have demonstrated inhibition of TAF-induced angiogenesis by cartilage fragments[3] or extracts[4]. In this study we show that isolated chondrocytes can inhibit the angiogenesis induced by lymphocytes *in vivo*. Their ability to do so depends on the ratio of chondrocytes to lymphocytes used.

LIA assays were performed in 8–10-week-old female (CFW × C57Bl/Sn)F_1 hybrid mice. Recipients were injected intradermally with 0.1 ml of Hanks solution containing from 1.0×10^6–4.0×10^6 viable lymphoid cells obtained from 8–10-week-old parental CFW female donors by mechanical disruption of the spleen in a loose-fitting glass homogeniser. Control injections contained 4×10^6 viable syngeneic F_1 spleen cells or 4×10^6 parental CFW thymocytes.

Chondrocytes were obtained from cartilaginous epiphyses of long bones dissected from 6–10-d-old CFW mice. Cartilage fragments were digested with a mixture of 0.25% collagenase, 0.25% trypsin and 0.05% streptodornase in Hanks solution[5]. Cells liberated from the matrix were rinsed three times in Hanks solution with 30% calf serum and then twice in Hanks solution alone. Viability, estimated with the Trypan blue exclusion test, was greater than 85%.

To measure the effect of chondrocytes on lymphocyte-induced angiogenesis, variable numbers of viable chondrocytes (from 0.2×10^6 to 2.0×10^6) were mixed with 4×10^6 viable syngeneic or parental spleen cells in a total volume of 0.1 ml of Hanks solution to obtain a chondrocyte–lymphocyte ratio of 1 : 20, 1 : 10, 1 : 5 or 1 : 2 respectively. Control injections consisted of chondrocytes only or of spleen cells mixed either with freeze–thaw killed chondrocytes or with viable kidney cells obtained from adult CFW donors by digestion with the enzymatic solution used for chondrocyte isolation. Trypan blue (2–3 drops) was added per 1 ml of each inoculum injected to facilitate the subsequent location of the injection site. To eliminate the possibility of individual recipient variations in reactivity, each animal received up to 8 different inocula, tested in a coded manner. The animals were killed after 3 d and the skin carefully dissected from the underlying muscles to expose its inner surface under a dissecting microscope using a green filter. All blood vessels directed towards the injection site and contrasting with the background vasculature because of their contorted shape and pathways were scored according to the criteria proposed by Sidky and Auerbach[1]. The number of vessels evoked by intradermal injection of parental spleen cells compared with other cell types is shown in Table 1.

The lymphocyte-induced angiogenesis assay used in the present study is a lymphocyte-dependent at least initially, when there is lymphocyte contact with the host antigens. Specific recognition by competent cells must first take place to induce neovascularisation, since the angiogenesis evoked by syngeneic F_1 spleen cells is negligible. Also, angiogenesis induced by parental thymocytes is weaker than that induced by parental spleen cells. Lymphocytes stimulated by host antigens may release angiogenetic factors or, alternatively, these factors could be products of tissue destruction resulting from an immunological reaction. Lymphocytes also produce substances chemotactic for granulocytes[6,7] and polymorphonuclear leukocytes have been shown to evoke angiogenesis in the rabbit cornea[8]. However elicited, the stimulatory effect on capillary growth is related to the number of the competent lymphocytes injected.

These results show that chondrocytes, in appropriate concentration, inhibit the angiogenesis induced by lymphoid cells. At a chondrocyte–lymphocyte ratio of 1 : 10 this effect is most marked, reducing the intensity of the angiogenetic response evoked by 4×10^6 spleen cells to a level similar to that produced by 2×10^6 spleen cells. This effect is specific for viable chondrocytes since neither killed chondrocytes nor kidney cells show this inhibitory effect on angiogenesis.

Isolated chondrocytes produce matrix when injected into recipient animals[5] and some of their products could affect endothelial cell growth. Small cationic proteins with protease-inhibiting properties have been shown to be responsible for the resistance of cartilage to invasion by vascular mesenchymal cells[9,10]. Cartilage extract inhibits the growth of endothelial cells *in vitro*[11]. Cartilage fragments or extracts inhibit TAF-induced neovascularisation *in vivo*[3,4] and cartilage tumours are the least vascularised of all tumours tested[12]. The inhibitory effect of chondrocytes thus seems to be similar regardless of the type of stimulus used to induce neovascularisation. The stimulatory factors may be produced by lymphocytes as lymphokines or their production may be lymphocyte dependent. In practice, tumour-induced and lymphocyte-induced angiogenesis are indistinguishable[13]. TAF has been isolated from tumour cells[2] but in many tumours the extent of lymphocytic infiltration is rather high[14]. Tumours do not grow well in the

anterior chamber of the eye or in perfused organs[15] where the access of lymphocytes to tumour cells is prevented. A rare spontaneous tumour growth in nude mice[16] could support this assumption, favouring Prehn's immunostimulation theory[17].

We found that at higher chondrocyte–lymphocyte ratios (1 : 5 or 1 : 2) an increase of angiogenesis rather than inhibition was seen, suggesting that an immunological reaction may be occurring against tissue-specific antigens on the chondrocyte surface. It has been shown that syngeneic rat chondrocytes can evoke an immune response suggesting that these chondrocytes possess a sequestered antigen[18–20]. The same is probably also true for murine chondrocytes.

Therefore, when chondrocytes and lymphocytes are mixed, two different processes may occur. At low ratios primarily an angiogenesis-inhibiting process occurs, but at higher ratios this is overcome by the increased production of lymphocyte-angiogenetic substances directed against chondrocyte-specific antigens which increases new blood vessel formation, rather than decreases it as would be expected.

The finding that viable chondrocytes can inhibit new blood vessel formation has some morphogenetic implications for osteogenesis. Capillaries from perichondrium cannot penetrate cartilage anlages of long bones. When a number of chondrocytes die in the ossification centre, the local concentration of the inhibitory substance decreases, which might permit localised invasion of capillaries of the periosteal bud and thus initiate osteogenesis.

In addition, we have tested the effect of 1 M HCl–guanidine extract of human costal rib cartilage (obtained from biopsy) on mouse endothelial cell growth induced by local injection of allogeneic murine lymphocytes. This extract also inhibited endothelial cell growth (unpublished) showing that the cartilage inhibitory effect can act across the xenogeneic barrier.

Human smooth muscle autoantibodies reacting with intermediate (100 Å) filaments

THE specificity of human smooth muscle autoantibodies (SMA) is known only in chronic active hepatitis where SMA are of anti-actin type[1,2]. In other diseases there seem to be SMA of additional specificities[3–5]. Anti-actin antibodies react with microfilaments of cultured cells[6,7]. We describe here two human SMA-positive sera which react in indirect immunofluorescence microscopy (IFL) with other cytoskeletal structures, intermediate (100 Å) filaments. Such filaments are especially abundant in smooth muscle cells[8,9] but occur also in other cells including fibroblasts[10].

The SMA-positive sera were obtained from two cancer patients and reacted typically with smooth muscle tissue by indirect IFL technique[11] but could not be neutralised with purified actin. These sera reacted also with intercalated disks and the periphery of rat cardiac myofibrils. A similar

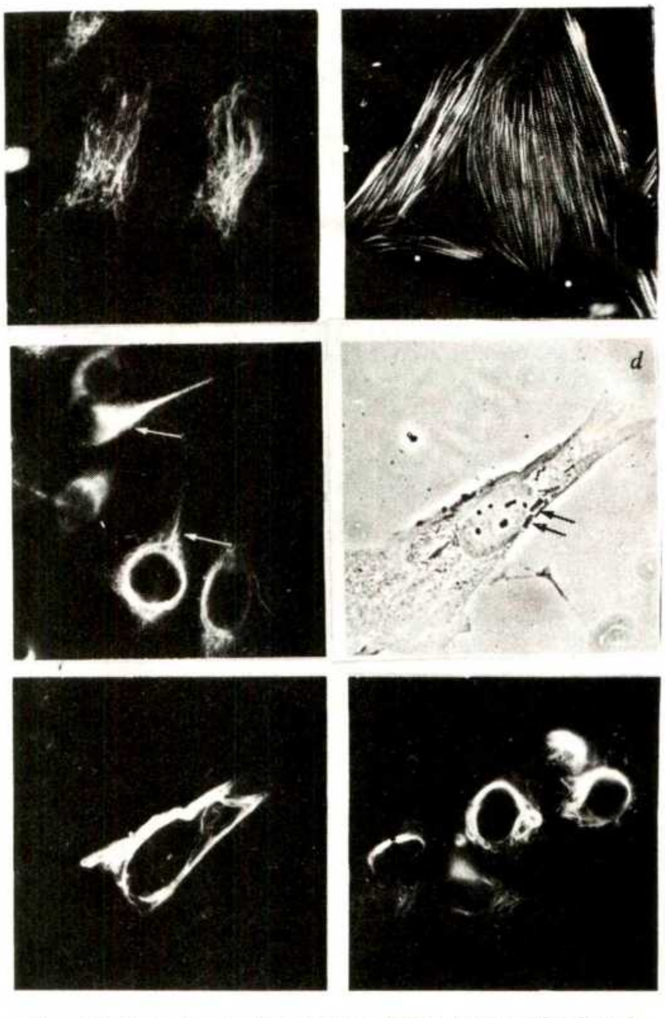

Fig. 1 Indirect immunofluorescence (IFL) staining of cultured cells with two human sera, one containing smooth muscle antibodies (SMA) to intermediate filaments (*a* and *c–f*) and the other to actin (*b*). Both sera had a SMA titre of 5,000 determined by indirect IFL using unfixed cryostat sections of rat stomach and kidney as substrates. To visualise human antibodies FITC-conjugated sheep anti-human immunoglobulin (NBL, Solna, Sweden, F/P molar ratio 2.9) was used. Human embryonic skin fibroblasts cultivated in RPMI 1640 + 10% foetal calf serum were used in their 10th to 25th passage *in vitro*. Mouse neuroblastoma cells were cultivated in MEM + 10% foetal calf serum. Cells were grown on cover slips for 48 h before fixation for 10 min in −20 °C acetone. *a*, Reaction of SMA of anti-intermediate filament type with fibroblasts. Note the fine fibrillar network in the cytoplasm. *b*, Reaction of SMA of anti-actin type with fibroblasts. The typical filamentous staining is seen. *c*, Reaction of SMA of anti-intermediate filament type with mouse neuroblastoma cells. Note the perinuclear bundles (arrows). *d*, A fibroblast, treated with vinblastine sulphate for 4 h (Lilly, 10 μg ml^{-1}), visualised in phase contrast microscopy. Tubulin containing paracrystals, induced by the treatment are indicated by arrows. *e*, The same cell as in (*d*) stained by SMA of anti-intermediate filament type. Coiling perinuclear bundles of fluorescence are seen. The paracrystals are not visualised. *f*, Reaction of SMA of anti-intermediate filament type with fibroblasts treated with demecolcine for 12 h (Colcemid, Ciba, 0.1 μg ml^{-1}). Thick coiling fluorescent bundles are seen at the perinuclear area also after this treatment.

staining pattern was recently reported by Lazarides and Hubbard[12] who used an experimental antiserum to 'desmin', a subunit protein of intermediate (100 Å) filaments.

In human embryonic skin fibroblasts our SMA-sera stained a fine fibrillar cytoplasmic network by IFL (Fig. 1*a*). This fluorescence pattern clearly differed from the microfilament staining produced by SMA of anti-actin type (Fig. 1*b*) and could not be inhibited with purified actin. A preparation of intermediate (100 Å) filaments isolated using the method of Cooke[8] completely inhibited both the fibrillar staining of fibroblasts and the staining of smooth muscle and cardiac tissues. To identify the fibrillar structures found in cultured fibroblasts by IFI we treated cells with cytochalasin B, vinblastine and demecolcine (Colcemid). These drugs induce typical alterations in the cellular cytoskeleton[10,13]. Cytochalasin B characteristically abolished the filamentous staining obtained with anti-actin antibodies but the fibrillar staining was not affected. Treatment with vinblastine resulted in the formation of paracrystals which are known to contain tubulin[14]. These remained unstained by IFL (Fig. 1 *d*, *e*). Instead, in cells treated either with vinblastine or demecolcine perinuclear coiling bundles were seen (Fig. 1*e*, *f*). Such bundles, induced by microtubule-disrupting drugs, consist of intermediate filaments[10]. This was confirmed in our study by electron microscopy of demecolcine- (Fig. 2) and vinblastine-treated cells.

When cultured mouse neuroblastoma cells[15] were stained by IFL, bright perinuclear bundles were seen (Fig. 1*c*). The bundles were similar to those observed by Jorgensen *et al.*[16] who used antibodies specific for a subunit protein of neurofilaments. The reaction of our sera with neuroblastoma cells corroborates the recent suggestions that neurofilaments and intermediate filaments are identical[16,17].

Our results show that treatment of cells with drugs characteristically altering intracellular organisation offers a method in studies of autoantibodies reacting with cytoskeletal structures. Using this approach we have found that some SMA react with autoantigens located in intermediate filaments. Thus far only one component of the intermediate filaments has been described, desmin[12] or skeletin[9], having a molecular weight of between 54,000 and 55,000. Whether our sera contain antibodies against this protein is not yet known.

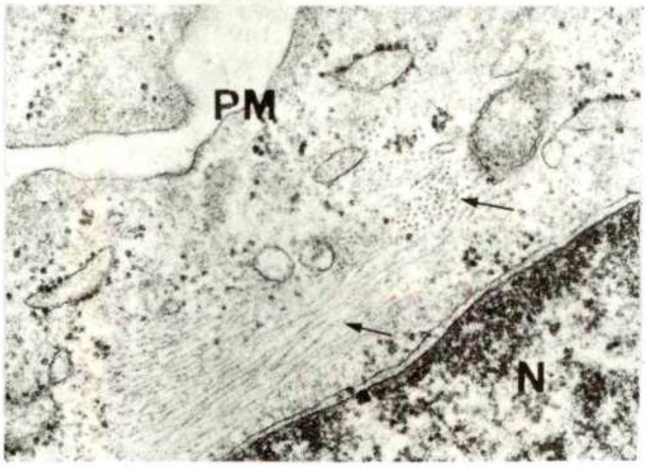

Fig. 2 An electron micrograph of a cell treated with demecolcine ($0.1\ \mu g\ ml^{-1}$) for 12 h. For electron microscopy the cultures were fixed in 2.5% glutaraldehyde buffered with 0.1 M sodium cacodylate (*p*H 7.2), postfixed in 1% osmium tetroxide and embedded in Epon 812. Thin sections were transversally sectioned from cultures and post-stained with uranyl acetate and lead citrate. Electron microscopy was done at the Department of Electron Microscopy, Helsinki University. Bundles of filaments, 10 nm in diameter, are seen perinuclearly both tangentially and transversally sectioned (arrows). N, Nucleus; PM, plasma membrane. × 39,000.

Intermediate filaments have been studied mainly by electron microscopy[10,18,19]. Human autoantibodies offer an additional tool to study the function and suggested identity of these filaments in different cells.

Myogenic defect in human muscular dystrophy

THE aetiology of muscular dystrophy has been considered to be either myogenic or neurogenic[1]. Much of the evidence has been obtained from studies of muscle in tissue culture using animal[2] or human[3] sources. Although results have often been equivocal[4,5] the most recent studies have failed to show any morphological differences between normal and abnormal muscle[3,6,7]. Hence, it could be argued that the primary defect is not in the muscle but rather may be in the nerve which innervates the muscle[6]. But, almost all of these studies have involved techniques based on explants of small muscle pieces, which muscle fragments then typically require one week for outgrowth from the tissue pieces and a further week or two before differentiated function (myotube formation) is seen[3,6]. For expression of maximally differentiated cultures (cross striations and spontaneous contractions) it has been presumed that innervation may be required, since contractions are rarely found and are essentially seen only in the presence of added nerve cells[6]. We have recently described a new technique for establishing fully differentiated adult muscle cultures from mononucleated cells and have found spontaneous contractions without the requirement for nerve cells[8]. Using this method, we have compared the maturation of muscle from the Duchenne (X-linked recessive) form of muscular dystrophy with appropriate control cases, and have found an abnormality in cellular behaviour restricted to the Duchenne material.

Table 1 shows the results from cultures of nine dystrophic patients and nine controls and demonstrates that in each case the abnormal formation of clustered cells occurs before the appearance of myotubes. It also demonstrates that the level of creatine phosphokinase (CPK) specific activity is generally lower than in controls. The first sign of abnormality can be detected as early as four days after plating the cells and consists of areas where the cells are clustered together in close proximity (Fig. 1*a*) rather than being more uniformly distributed in a monolayer (Fig. 1*b*). Some of the cells in the clusters had a superficial resemblance to fibroblasts, but more careful examination revealed that they were quite atypical in their morphology. The nuclei of these cells as well as the perinuclear cytoplasm seemed to be increased in size and hence might be termed hypertrophic, as previously described[9,10]. They also have longer processes (Fig. 1*a*). There is, however, a proportion of myoblasts which fuse in apparently normal fashion.

With further differentiation there are a certain number of refractile myotubes but their distribution is again abnormal in that they typically span the gap between two of the multilayered cell clusters which are by now several cells thick (Fig. 1*c*) and thus give the appearance of a pyramidal form of multicellular complex when one focuses up and down along their margins. Of course, the photographs do not directly reveal this third dimensional consideration. The clear areas on the surface of the culture plate between the hypertrophic clusters are still prominent at this stage, which is again quite different from the normal muscle (Fig. 1*d*) or from the other diseases referred to previously. Within these cases there was no obvious correlation between the degree of connective tissue found in the biopsy and the degree of cluster formation; quite the contrary—the patient (M.C.) with a massive excess of fibroblast infiltration took the longest time (Table 1) to exhibit the abnormality.

Although there have been various comments on the behaviour of dystrophic muscle in culture, other authors have not described these particularly early abnormal events during the maturation sequence. It is thus quite different from the normal sequence whereby single myogenic cells fuse into multinuclear myotubes and then differentiate into fully refractile muscle straps[11]. Those techniques which initiate cultures from small explants of tissue pieces have a requirement for cell migration from the initial explants, before the myoblasts can begin to fuse and form myotubes. This difference in the methods for starting the cultures may explain in part why explant techniques obscured these early events. But, the technique which starts with single cells does not select for cells which must migrate out of the explant before they can differentiate into myotubes. A closer approximation to starting cultures with single cells has been the technique which begins with smaller 'muscle cell pieces' ($60 \times 25\ \mu m$) each of which contains a few nuclei that grew initially by 'budding'[12]. This technique revealed some abnormal intracytoplasmic inclusions but the abnormalities in cellular distribution and myotube formations were not described[13].

Concerning the primary metabolic lesion, there are several possible defects in cellular metabolism which give rise to the abnormal muscle development (for example, membrane alterations[7,14,15]). But it should also be considered that the genetic defect may involve an abnormality of control gene which normally initiates a specific sequence (for example, during the orientation of thick and thin filaments) during cellular differentiation[16].

It should not yet be concluded that the abnormalities are diagnostic for Duchenne dystrophy. The origin of the cells may be an abnormal form of fibroblastic connective tissue. They may also be aberrant precursors of myoblasts, however.

The advantages of the current technique are that one has ilve cells which can be collected for specific metabolic assays, that certain cells display an unusual form of cell–cell interactions, that the cells within the unusual clusters do not seem to resemble normal fibroblastic or epitheliod morphologies[17] and that the complete sequence of muscle maturation[11] can be observed and sampled at appropriate developmental times. Further, since these abnormalities

are found in the absence of any nerve cell input, at least this portion of the genetic defect is myogenic rather than neurogenic.

Clearly, further work is required to specify the precise biochemical alterations associated with these abnormalities in the initial cell appearance, their subsequent intercellular behaviour (and possibly cell membranes[7]) as well as their final degree of differentiation, including response to co-cultured nerve cells.

A human leukaemic cell expressing hybrid membrane phenotypes

INDIVIDUAL surface markers differentiate B and T cells with varying degrees of certainty, and it is generally agreed that a panel of immunological markers is required to assign a particular cell to a category[1]. In general, the ability to form spontaneous sheep red blood cell rosettes (E) and to react with anti-T-cell antisera are characteristics of T lymphocytes, whereas B lymphocytes are characterised by the presence of surface immunoglobulin (SmIg), C3 and Fc receptors and the presence of Ia-like antigens on the cell membrane[2,3]. However, in some instances lymphocytes are detected which exhibit combined B- and T-cell markers[4]. This has been particularly true in the case of human leukaemic cells, where a variety of unusual combinations of phenotypic markers has been described[5,6]. In this communication, we report on a human leukaemic cell from a case of hairy cell leukaemia[7–9] (HCL) with unusual combined B- and T-cell membrane characteristics.

In Table 1, data are presented on the surface marker characteristics of the unusual hairy cells (HCs) from peripheral blood and spleen when tested over a period of two months. Although the expression of these individual B and T phenotypic markers fluctuated over this time, a significant overlap was found in the values obtained when the T cell markers (E-rosetting and anti-T cell serum) and the more conventional B cell markers (SmIg, Fc(γ) and the Ia-like protein complex P29/34) were compared. The summation of these B- and T-cell markers greatly exceeded 100%. This contrasts with the only reported case of a biclonal T- and B-cell leukaemia, in which the two clones independently expressed B and T membrane phenotypes[10]. In addition to the data presented in Table 1, the cells were found to be negative for the C3b receptor[4] and the EB virus nuclear antigen (EBNA)[11], but did form spontaneous rosettes with mouse erythrocytes, a marker for a subpopulation of B cells[12] (1–9% with peripheral blood cells and 47% with splenic cells). In the spleen cell preparation, which was shown to contain >95% HCs, 95% of the cells were stained for intracytoplasmic IgM, IgG and *k* chain, of which 25% formed an intense patchy staining with FITC-labelled anti-IgG and anti-IgM. The finding of a receptor for IgM (Table 1) on these cells is not surprising, since this receptor is present both on a subpopulation of normal T lymphocytes[13] and on the pathological cells of some B-cell leukaemias[14] including HCL (ref. 9). The distinctive hairy appearance of the pathological cells of HCL enabled easy recognition of these cells both at light and electron microscope level in the various marker studies.

Table 1 Cell surface marker studies* on isolated mononuclear cells from peripheral blood and spleen

*Peripheral blood (PB) mononuclear cells were separated by Ficoll–Hypaque centrifugation; a splenic cell suspension was prepared by forcing pieces of fresh spleen through a wire mesh and the mononuclear cells isolated using a Ficoll–Hypaque mixture. E-rosettes were performed by the method of Kaplan and Clarke[19]; the specific rabbit anti-T serum[20] (a gift from Dr G. Janossy) was employed using an indirect fluorescent method; SmIg was detected either by the rosette method of Ling *et al.*[21] (purified sheep antisera a gift from Dr N. Ling) or by direct immunofluorescence (rabbit antisera a gift from Dr J. Smith); the Fc(μ) receptor was detected using rabbit IgM by the rosette method of Burns *et al.*[9]; the Fc(γ) receptor was detected using rabbit IgG by a rosette method; rabbit antiserum to purified human P29/34 (ref. 21) (a gift from Dr T. Springer) was used in an indirect fluorescent method (positive controls performed with B-cell leukaemias and negative controls with a T-cell line and a case of T-cell Sezary syndrome).

†Not done.

In the experiments to detect SmIg, a pre-incubation period of 1–2 h at 37 °C was routinely adopted, and the cells were observed to express SmIg of a single light chain type (*k*), of which IgD (*k*) was shown to persist after seven days in culture. The SmIg could also be removed by capping with anti-*k* chain serum. These points make it unlikely that SmIg can be attributed to cytophilic Ig or to autoantibody against the leukaemic cell.

To establish the nature of the E-rosette, a variety of blocking and inhibition experiments were carried out (Table 2). Whereas E-rosette formation was blocked by the anti-T-cell serum (although this antiserum did not interfere with the detection of SmIg) it was not blocked by the anti-P29/34 serum. Furthermore, a reduction in E-rosette formation by HCs, similar to that seen with normal T lymphocyte controls, was observed when rosette formation was carried out at 4 °C, with and without centrifugation, and in the presence of sodium azide or cytochalasin B. Thus, like E-rosette formation by normal T lymphocytes[15], this E-rosette formation was energy dependent and required an intact microfilament system. In addition, E-rosette formation was not markedly blocked either by group A substance from human saliva (which would block antibody activity against a heterophile antigen) or by treatment with anti-Ig sera. In the latter case, a SmIg receptor for sheep erythrocytes was further excluded by removing SmIg in a 'capping' process. In conditions in which no *k* chain was detected on the cell, E-rosette formation still occurred and, in some instances, the number of leukaemic cells rosetting with erythrocytes rose significantly.

HCL, a chronic leukaemia related to chronic lymphocytic leukaemia, is now considered to be a B-cell neoplasm[7,8] but the cells have been reported as possessing a

number of monocytoid features such as adherence to glass and phagocytic ability[7–9]. Furthermore, the pathological cells of most cases of HCL are of indeterminate maturity since they show such features of immaturity as poorly condensed peripheral nuclear chromatin[9] and the absence of a receptor for cholera toxin[16]. The nature of the disease, however, and the capacity to produce Ig for secretion suggests involvement of a mature cell type. It may not be surprising, therefore, that a cell of mixed B and T phenotype should appear in a leukaemia which is unusual in so many other ways, and it may indicate that the neoplastic transformation occurs at a point close to the divergence of B and T cells from the common haemopoietic stem cell. Alternatively, it may be that the genes controlling the expression of receptors for T-cell antigen have become derepressed by the neoplastic process acting on the HCs although derepression by EB virus is less likely due to the absence of EB nuclear antigen in these cells.

The argument of gene derepression has been proposed as the mechanism in the only previously described case of a human leukaemic cell, from a case of lymphosarcoma cell leukaemia, which possessed both SmIg and T-cell features[17]. Although there are some reports of leukaemic cells both forming E-rosettes and possessing receptors for Fc or C3, (refs 5, 6), there is evidence that subpopulations of normal lymphocytes also possess these marker combinations[4] and such leukaemias may be an amplification of these minor subpopulations. No normal lymphocyte population bearing the marker characteristics of the leukaemic cells in this report has yet been described in man, but such cells may exist in the mouse[18].

In conclusion, a case of HCL is described in which the pathological cells were shown to be E$^+$, anti-T$^+$, Fc(μ)$^+$, SmIg$^+$, cytoplasmic Ig$^+$, P29/34$^+$, Fc(γ)$^+$, mouse erythrocyte rosette$^+$, C3b$^-$ and EBNA$^-$. This observation emphasises the importance of using a large panel of immunological markers when studying membrane marker characteristics on haemic cells from both the normal and leukaemic situation. Indeed, cases of this kind could reveal further information on the nature of the leukaemic transformation and the study of such leukaemic cells may well lead to the identification of subpopulations of normal haemic cells.

We thank Dr Tim Springer for the anti-P29/34 serum and for discussion. This work was supported by grants from the MRC (G.F.B.) and the Leukaemia Research Fund (A.A.N., C.P.W.).

Epidermal Langerhans cells bear Fc and C3 receptors

THE mammalian epidermis contains a system of dendritic cells, eponymously referred to as Langerhans cells, whose functions are obscure. It is, however, accepted that Langerhans cells are of mesenchymal origin and since they are known also to occur in the dermis, lymph nodes, thymus, and other organs, the concept of Langerhans cells has widened to encompass a cellular system populating the connective tissues and certain stratified squamous epithelia of mammals[1]. Among the many hypotheses about their biological significance they have been considered to represent immunocompetent cells or cells which might capture antigenic materials[2], but there is insufficient evidence for this. Lymphocytes have been observed to be closely associated with Langerhans cells in delayed type hypersensitivity reactions to dinitrochloro-benzene in guinea pigs[3]; and when guinea pigs passively sensitised with lymphocytes from ferritin-hypersensitive donors, were challenged with ferritin, ferritin-containing Langerhans cells were observed in the draining lymph nodes of the challenged animals[4]. Metals and certain amines have an affinity for Langerhans cells *in vitro*[5], but since they can phagocytose ferritin and other substances without previous sensitisation[1], doubt remains whether they are immunologically engaged in the uptake and transport of potentially antigenic material. If Langerhans cells are indeed involved in immunological reactions, they should bear some of the surface markers characteristics of cells with known immunological functions, and we have now shown that they carry receptors for Fc and C3.

Epidermis of human volunteers was separated from the dermis, *in vivo*, using a suction blister device[6], washed in Medium 199 (Flow Laboratories, Irvine, UK), and dissociated, *in vitro*, with 0.5% trypsin (Flow Laboratories, Irvine, UK) in phosphate-buffered saline (*p*H 7.2) for 30 min at 37° C. Epidermal cell suspensions were prepared by teasing and pipetting the epidermal specimens gently in Medium 199 supplemented with 50 mg ml^{-1} gentamycin and 20% foetal bovine serum. After a double rinse and resuspension, the viability of the epidermal cells, checked by Trypan blue exclusion, ranged from 92 to 96%. The epidermal cells were then incubated with indicator reagents for Fc and C3 receptors, according to rosette assays described previously[7]: equal amounts of the epidermal cell suspension ($5–10 \times 10^6$ cells per ml) and of a 1% suspension of either IgG coated bovine red blood cells (EA-IgG) or IgM and complement-coated bovine red blood cells (EAC) were mixed, centrifuged and then incubated at 0 °C for 1 h. Any cell binding three or more erythrocytes was scored as positive, a minimum of 200 cells being counted.

Multiple experiments consistently showed that 3–4% of the cells in the epidermal cell suspensions formed rosettes with the EA-IgG and the EAC reagent. Rosetting was not seen in the controls, which included incubation of epidermal cells with untreated bovine red blood cells (BRBC); BRBC coated with IgM antibody (EA-IgM); EA-IgM incubated with heat-inactivated or EDTA-inactivated fresh mouse serum; in the case of EA-IgG, epidermal cells pre-incubated with 10 mg ml^{-1} heat aggregated human IgG or reacted with BRBC, coated with Fab$_2$ fragments of anti-BRBC IgG antibody. For this purpose the IgG anti-BRBC antibodies were pepsin digested according to Nisonoff *et al.*[8] and passed over a Protein A column (Protein A Sepharose CL 4B, Pharmacia, Uppsala, Sweden) to remove possible residual intact IgG molecules. BRBC coated with this Fab$_2$ antibody preparation (adjusted to the protein concentration of the original total IgG preparation) displayed no reactivity with either mononuclear blood cells or cells from epidermal cell suspensions.

Since the demonstrations of EAC rosettes after trypsin treatment contrasts with reports that EAC receptors on leukocytes are trypsin sensitive[9], the influence of our trypsinisation procedure was checked on peripheral mononuclear cells. Whereas a 0.005% concentration of trypsin destroyed the C3 receptors on lymphocytes, EAC rosette formation with latex-ingesting monocytes was still detectable after treatment with 0.5% trypsin. Thus, the trypsin sensitivity of EAC rosette-forming cells from epidermal cell suspensions corresponded to that of latex-ingesting monocytes from the peripheral blood.

To determine the nature of the subpopulation of epidermal cells showing EA-IgG and EAC rosette formation, smears were prepared from cell suspensions treated with EA-IgG and EAC and incubated according to a modified[1] Wachstein and Meisel cytochemical technique[10] for the demonstration of nucleosidetriphosphatase (NTP). This enzyme is, in the conditions used, a cytochemical marker for Langerhans cells[1]. All rosette-forming cells of the epidermal cell suspensions were reactive for NTP, whereas the non-rosetting cells failed to show enzymatic activity. In addition, epidermal cells pelleted after exposure to the EA-IgG reagent were processed for electron-microscopy, either directly or after pre-incubation for NTP cytochemistry. At the ultrastructural level, all rosette-forming cells exhibited NTP activity, whereas non-rosetting cells did not; rosetting cells exhibited the classical ultrastructural morphology of LC, including the typical LC cell granules (Fig. 1), whereas non-rosetting cells showed morphological features of either keratinocytes (keratinising epidermal cells) or melanocytes. These results show that the subpopulation of epidermal cells which have the receptor for Fc and C3 are Langerhans cells.

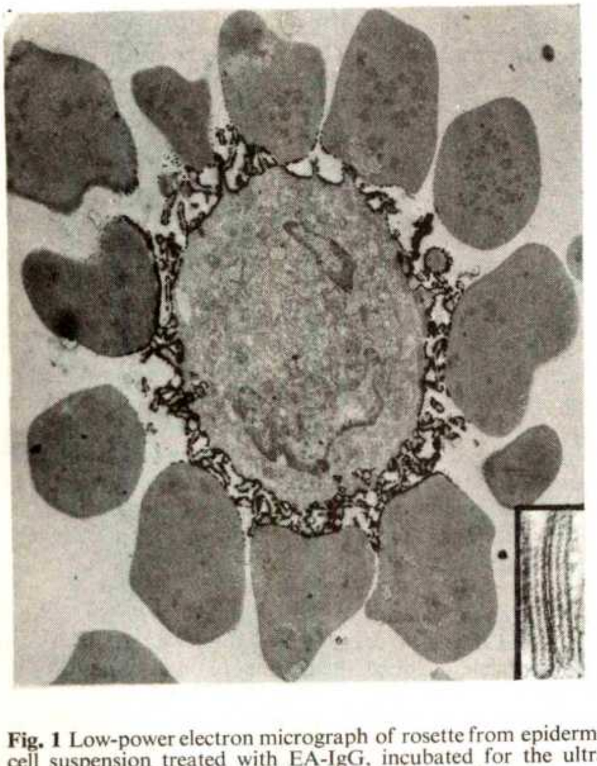

Fig. 1 Low-power electron micrograph of rosette from epidermal cell suspension treated with EA-IgG, incubated for the ultrastructural demonstration of NTP, and processed for electron microscopy. The rosetting, Fc receptor-bearing cell exhibits a folded nucleus, dendritic and villous surface projections, reaction product indicating NTP activity on its membrane and typical Langerhans cell granules in its cytoplasm (inset).

Fc and C3 receptors are known to occur on lymphocytes[11], on monocytes–macrophages histiocytes[12], and, as recently shown, on isolated hepatocytes[13]. Since Langerhans cells bear neither morphological nor cytochemical characteristics of lymphocytes[1] and since preliminary studies in our laboratories indicate that they exhibit neither membrane immunoglobulins nor E receptors, they do not qualify as lymphocytes. On the other hand, their Fc and C3 receptors make them reasonably good candidates for inclusion in the monocyte–macrophage–histiocyte series of cells despite the fact that, in phagocytosis experiments, *in vivo*, they fail to exhibit greater phagocytic capacity than the other cells of the epidermis[14]; also, the morphological identity of Langerhans cells with certain histiocytic cells in histiocytosis X (refs 1, 15) a proliferative histiocytic disease in man, is a good morphological correlate to these immunological findings. Our findings thus provide evidence for previous suggestions[2,4,5] that Langerhans cells perform macrophage-like functions.

The cells of the monocyte–macrophage histiocyte system are known to have an important role in immune reactions. They are responsible for the uptake, processing, and transfer of antigens to immunocompetent lymphocytes[16,17], and they are involved in T–B interactions[18]. The biological role of their Fc and C3 receptors is not entirely clarified, but they seem to mediate antibody-dependent cellular cytotoxicity[19] and the phagocytosis of immune complexes, whereby the C3 receptors bind C3 sites of immune complexes, and the Fc receptors are responsible for the ingestion phase[20]. The antibody-binding capacity of macrophages may thus regulate the inductive phase of the immune response since cell-bound antibody can mediate the presentation of antigen to T lymphocytes[21].

It does not appear unreasonable to assume that LC by means of their immunological receptor sites, perform functions similar to those of the monocyte-macrophage-histiocyte system, both by initiating the immune response to external antigens and by facilitating an enhanced reaction in the secondary response. These functions could thus provide a reasonable explanation for the paradox that Langerhans cells, as mesenchymal cells, are located in the most peripheral, ectodermal tissue of the mammalian organism, in the epidermis. If our conclusions are correct Langerhans cells may represent the most peripheral outpost of the afferent limb of the immune system.

Ia antigen expression on human epidermal Langerhans cells

It has been proposed that the mammalian epidermal Langerhans cell is an epidermal equivalent of the cells of the reticulo-endothelial system, which are involved in binding and presentation of allergens in lymph nodes and the spleen[1,2]. The demonstration that these resident cells are capable of binding various allergens and migrate to the lymph vessels and local draining nodes, indicates a major function in the afferent arm of the primary immune response[3,4] and has improved understanding of contact allergic hypersensitivity reactions. Much still remains to be discovered concerning the characteristics of the cell type, its reactivity with various antigens, and its relationship to other cells of the immune system. We show here that epidermal Langerhans cells react positively by immunofluorescence with antisera raised in rabbits against human B lymphoblastoid cell line membrane glycoproteins, which indicates the presence of Ia-like antigens on these dendritic cells.

The Ia antigens are surface glycoproteins associated with particular groups of immunologically active cells[5-7]. Although they have been detected in small quantities on T cells they seem to be associated primarily with B cells[8,9]. Recent studies have, however, shown them to also be expressed on macrophages[10], sperm, foetal liver cells and epidermal cells[11]. This last group is intriguing, since the observation was made by means of cytotoxic assays. Thus, no morphological distinction was made between the various cell types present in the epidermis. The proposal that Langerhans cells are a kind of histiocyte and the evidence pointing to the presence of significant numbers uniformly distributed in the epidermis[12], suggested that they might express Ia antigen. Since the functional significance of Ia antigens is not yet clear, confirmation of this proposal might have important implications. Ia antigens have been shown to be involved in mixed lymphocyte reactions (MLR)[13,14], graft-versus-host (GVH) reactions[15], skin graft rejection[16] and a variety of other cooperative phenomena.

Human B-lymphocyte Ia antigens were isolated from B lymphoblastoid cell lines (Fig. 1). The final protein peak used for production of rabbit heteroantisera, had a molecular weight of 33,000 daltons. The heteroantiserum after absorption with a human T cell line (MOLT 4), was shown to react against B cells but not T cells or thymocytes. When incubated with lymphocytes in the MLR, the antiserum suppressed thymidine incorporation. In precipitin analysis in Ouchterlony plates, a rabbit antiserum to HL-B antigens (Dr H. Kunkel, Rockefeller University), showed immunological identity indicating a relationship to the Ia system.

Human skin obtained at surgery was frozen and 5-nm sections were prepared for direct and indirect immunofluorescence (IF) with the rabbit anti-Ia IgG fraction. Table 1 illustrates results of the various IF tests performed.

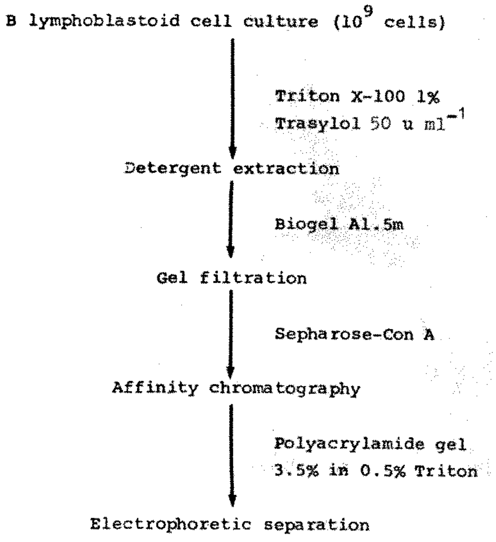

Fig. 1 Scheme of fractionation.

The findings can be summarised as follows: dendritic cells in the suprabasal zone of the human epidermis stain strongly at titres down to 1/1000 (Fig. 2). Specific immune blocking and pre-incubation with antigen confirmed the specificity of the reactions. The possibility that Fc receptors on Langerhans cells might nonspecifically bind immune reagents was tested using Fab′ fragments of the rabbit anti-Ia antiserum. Positive staining was maintained using this reagent. Experiments to demonstrate either Fc receptors or receptors for C'_3 using EA and EAC rosetting methods[18] on frozen sections were negative. Other workers have failed to show binding of EA rosettes to cells in the epidermis, that might be interpreted as Langerhans cells (R. Edelson, personal communication).

In order to study further surface receptors on Langerhans cells a cell suspension of EDTA separated epidermis was prepared by 30-min incubation at 37 °C in 0.5% buffered trypsin. Epidermal cell suspensions were checked for viability, for morphology with haemotoxylin and eosin, for ATPase staining and for the presence of Fc and C_3 receptors. EA (IgG) and EAC (IgM) rosetting methods were carried out on the cell suspensions with appropriate controls, that is, untreated SRBC and EA (IgM). With both EA and EAC methods between 2–3% of the cells formed rosettes of 5+ SRBCs. Rosetting was not seen in any of the controls. Thus cell suspensions of the epidermis prepared with trypsin demonstrate a small percentage capable of forming rosettes, indicating the presence of Fc and C'_3 receptors on their surface.

GAR-FITC: IgG fraction goat anti-rabbit IgG conjugated to fluorescein isothiocyanate.

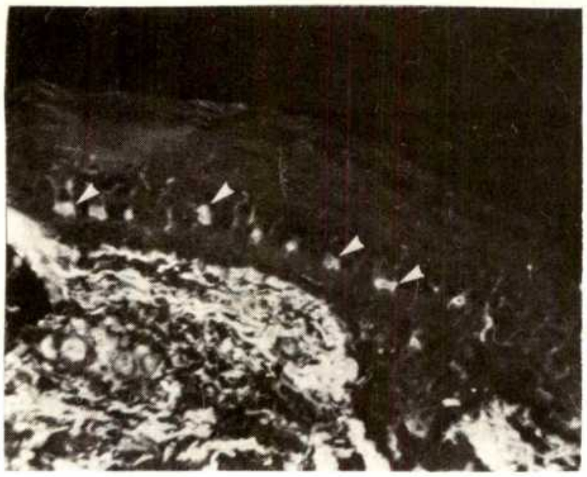

Fig. 2 Indirect immunofluorescence staining of normal human skin. Rabbit anti-human Ia (gG fraction) followed by goat anti-rabbit IgG–FITC positively stained suprabasal dendritic cells. ×238 (arrows).

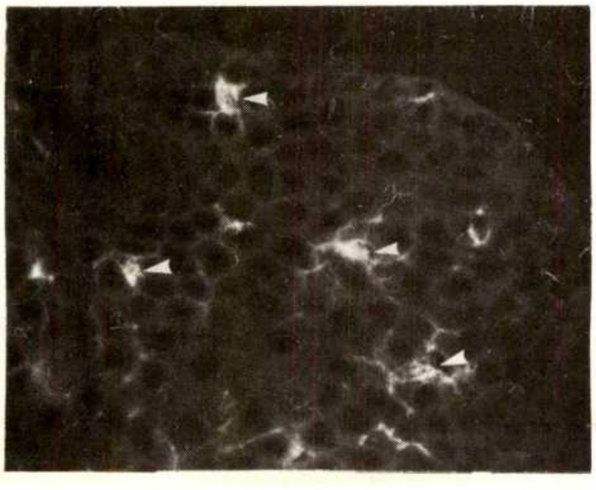
In addition, the same approximate percentage of cells show staining for ATPase and for Ia antigen as carried out by fluorescent microscopy. Simultaneous demonstration of the two reactions has not yet been achieved, but seems to be technically feasible.

As might be predicted from the information concerning distribution of Langerhans cells in leukodermatous[19,20] conditions such as vitiligo and halo nevi, staining reactions were noted not only in the suprabasal location but also in the basal layer. Furthermore there was no cross-species reactivity since Langerhans cells in rodent keratinising epithelia did not stain.

These observations suggest that if the Langerhans cell is a histiocyte, it is atypical, since it does not seem from frozen sections, to express either Fc or C'_3 receptors that are detectable by rosetting, nor is it very phagocytic[21]. Clearly the disparity in the detection of surface receptors on isolated cells as opposed to frozen sections can be explained either by the sensitivity of the methods or because of an unmasking effect of the trypsinisation. Whether the cells *in vivo* express these surface receptors requires further investigation. The specific staining with anti-Ia antisera should provide a tool to assist in the isolation of the Langerhans cell.

To confirm these findings ultrastructurally, we are using Fab′ fragments of the anti-Ia antiserum labelled with ferritin in electron microscopic studies. Preliminary results demonstrate a weak but specific staining of the membranes of epidermal Langerhans cells. In the same studies dermal histiocytes and some lymphocytes also show specific staining. Clearly the present identification of positively stained cells in the epidermis as being Langerhans cells relies heavily on the established suprabasal localisation in normal tissue and is supported by the changes in distribution seen in leukodermatous skin. The cells as shown in a tangential section are clearly dendritic (Fig. 3). ATPase-stained tissue sections show an identical distribution pattern.

Fig. 3 Indirect immunofluorescence staining of a tangential section of normal human skin (as in Fig. 2). High magnification demonstration of dendritic cells. ×680.



These observations provide interesting avenues for research on the Langerhans cell itself, as well as confirming that they express surface antigens that have so far been associated with immunologically active cells. They also have a role with such cells in the rejection of skin grafts.

Epidermal Langerhans cells express Ia antigens

THE major histocompatibility complex (MHC) of mouse and man controls the expression of several cell surface antigens[1]. The classical transplantation antigens are present on most if not all adult, nucleated cells. However, molecules controlled by the immune response region of the MHC display a much more restricted tissue distribution. The immune response-associated antigens (the Ia antigens in the mouse and HLA-D antigens in man) seem to be integral parts of the plasma membrane of B and T lymphocytes, macrophages, spermatozoa, and epidermal cells[2]. The physiological role of the Ia antigens is far from understood but their participation in various immunobiological events is well documented (for a review, see ref. 3). In addition to their role as triggers in the mixed leukocyte reaction[4], the Ia antigens are required for collaboration between T and B lymphocytes[5] and between macrophages and T cells[6]. Since all known functions of the Ia antigens pertain to the immune system it seemed that they should be expressed on an epidermal cell population involved in immune reactions. We therefore set out to investigate which of the three cell types of epidermis, keratinocytes, melanocytes, and Langerhans cells, expresses the Ia antigens, and from the results of fluorescent antibody staining we conclude that it is the Langerhans cells.

Epidermal cells remove anti-Ia antigen antibodies from alloantisera[2] but no data are available as to the biochemical nature of the Ia antigen-reacting molecules in epidermis. To reveal the structure of these molecules biopsies of skin were obtained from patients undergoing surgery for mammary hyperplasia. The epidermis was separated mechanically from underlying dermis after heating the biopsies to 52 °C. The biopsies were treated by homogenisation on 0.02 M Tris-HCl buffer, *p*H 8.0, containing 0.15 M NaCl and 1% Triton X-100. Insoluble material was removed by centrifugation at 105,000*g* for 60 min and glycoproteins, present in the supernatant, were isolated on an affinity chromatography column containing covalently-bound Lens culinaris haemagglutinin[7]. Purified glycoproteins were labelled with ^{125}I and Ia antigen-reacting material was isolated by indirect immunoprecipitation using a specific rabbit anti-HLA-D antigen serum[8]. The immune complexes were dissolved and separated by SDS–polyacrylamide gel electrophoresis, as previously described[7]. Figure 1 shows that the anti-HLA-D antigen serum preferentially precipitated two types of polypeptide chains with the apparent molecular weights 28,000 and 34,000. This two-chain pattern is indistinguishable from that obtained when the same antiserum was used to precipitate molecules obtained from leukaemic B lymphocytes. However, two additional components with the apparent molecular weights 70,000 and 50,000, respectively, were also visualised. Since the same polypeptide chains were also present in precipitates generated by normal rabbit serum, it seems reasonable to conclude that they represent nonspecifically-precipitated contaminants. Thus, the result is consistent with the view that HLA-D antigens of epidermis have the same overall structure as their counterparts on B lymphocytes.

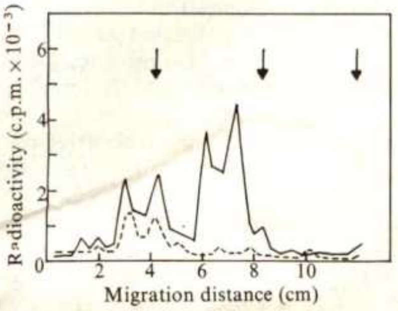

Fig. 1 SDS–polyacrylamide gel electrophoresis in reducing conditions of Triton X-100-solubilised, ^{125}I-labelled epidermal glycoproteins reactive with a rabbit antiserum raised against highly purified HLA-D antigens (———). Normal rabbit serum served as the control (— — —). The details of the experimental procedure have been outlined elsewhere[7]. The arrows denote the migration positions (from left to right) of marker heavy and light chains of human IgG and the marker dye bromphenol blue.

The type of cell in epidermis which expresses HLA-D antigens was examined with use of the IgG-fraction of a rabbit anti-HLA-D antigen serum. Biopsies of human skin were obtained from the wrist of healthy volunteers. Thin sections were prepared from the biopsies and the presence of HLA-D antigens was assessed by an indirect immunofluorescence technique, as described in the legend of Fig. 2. Antibodies against HLA-D antigens only stained a few cells in the epidermis. Figure 2 shows that the stained cells were confined to the suprabasal part of epidermis and that they displayed dendritic processes. The appearance of the stained cells as well as their localisation in the epidermis suggest that they are not keratinocytes. To demonstrate that the latter cell type does react with antibodies, thin sections of skin biopsies were stained with antibodies against β_2-microglobulin[9]. Since β_2-microglobulin represents the common subunit of the HLA-A, -B, and -C antigens[1], which are known to be present on keratinocytes, the antibodies should stain all cells in epidermis. Figure 2 demonstrates that antibodies against β_2-microglobulin gave a bright intercellular staining of all cells in the epidermis but dermis was not stained. The specificity of the antibody binding was assessed by replacing the antisera by normal rabbit gamma globulin. Figure 2 shows that normal rabbit gamma globulin did not stain any cells in the epidermis.

Since the above data clearly demonstrate that the HLA-D antigen-bearing cells are not keratinocytes an experiment was performed to investigate whether the antigens were present on melanocytes or Langerhans cells. Advantage was taken of the fact that the epidermis of albino guinea pigs virtually lacks melanocytes[10]. We have previously shown that the antiserum cross reacts extensively with murine[8] and guinea pig Ia antigens (L.K., unpublished observation). Despite the absence of melanocytes in the guinea pig epidermis staining of the HLA-D antigens gave a similar pattern to that observed for human epidermis. This demonstrates that the melanocytes are not responsible for the presence of Ia antigens in the epidermis. Thus, the observations that keratinocytes and melanocytes do not express HLA-D antigens and the dendritic appearance of the HLA-D-bearing cells strongly suggest that it is the Langerhans cells which express these antigens.

The function of the Langerhans cells is far from understood but they may represent macrophage-like scavengers with poor phagocytic activity[11]. The recent observations that the Langer-

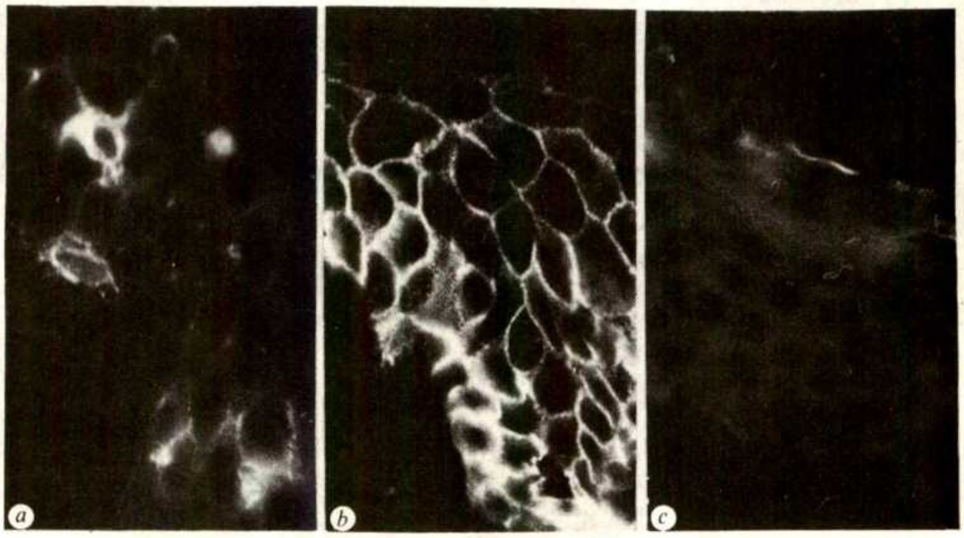

Fig. 2 Immunofluorescence of thin sections of skin biopsies after indirect staining with antibodies against HLA-D antigens (*a*) and β_2-microglobulin (*b*). In *c* normal rabbit gammaglobulin replaced the antibodies. Sections of 6 µm were prepared from skin biopsies. The air-dried sections were separately incubated with 50-µl portions of the IgG fractions from the antisera and normal rabbit serum. The IgG fractions were diluted in phosphate-buffered saline (*p*H 7.2) containing 4% of bovine serum albumin. The concentration of IgG was varied from 1 to 0.1 mg ml^{-1}. The antibodies were allowed to react with the skin sections for 30 min at room temperature in a humid atmosphere, then washed extensively in the phosphate buffer, and allowed to react with specific fluorescein–isothiocyanate-conjugated goat anti-human IgG at a working concentration of about 0.1 mg ml^{-1}. After an incubation period of 30 min and several washes the sections were mounted in 10% glycerol and examined in a Leitz Orthoplan fluorescence microscope with incident light and blue narrow band activation illuminated with a Philips × BO 75 lamp.

hans cells selectively take up antigens which are known to cause contact dermatitis[12,13] and the present finding that these cells express Ia antigens are in keeping with an immune function for the Langerhans cells. It is conceivable that the role of the Langerhans cells in contact dermatitis may be related to the following observations. It seems likely that T killer cells participate in contact dermatitis[13] but the generation of T killer cells is generally dependent on allogeneic differences involving the classical transplantation antigens as well as the Ia antigens[14]. However, chemically modified syngeneic cells may also give rise to the production of T killer cells that are directed against the individual's own transplantation antigens as well as to the foreign antigen[15]. The stimulation by the foreign antigen of the precursors of the T killer cells seems to require that the antigen is presented by macrophages expressing syngeneic Ia antigens[16]. Contact dermatitis may thus involve binding of the allergen to the Langerhans cells, which by their expression of Ia antigens may trigger antigen-specific T lymphocytes to become killer cells. These killer cells will subsequently react with any cell which expresses the syngeneic transplantation antigen together with the allergen. Since in epidermis Langerhans cells preferentially bind those antigens which are known to cause contact dermatitis the Langerhans cells should be the prime target cells. Interestingly, in contact dermatitis the number of Langerhans cells is reduced and the apposition of mononuclear cells to Langerhans cells has been observed[13].

Cytotoxicity against tumour-associated antigens not H-2 restricted

CYTOTOXIC thymus-derived lymphocytes (T cells) can be generated both *in vivo* and *in vitro* against many different types of cell surface antigen (reviewed in ref. 1). There have been several reports that when mice were injected with non-oncogenic viruses[2–4] or when spleen lymphocytes were sensitised *in vitro* against chemically modified syngeneic cells[5], the resultant cytotoxicity was directed only against target cells which shared with the sensitising and/or effector cells in the H–2K or H–2D region of the major histocompatibility complex (MHC). Similar observations have been made with several experimental tumour systems[6–10]. This indicates that the interaction between immune cytotoxic T lymphocytes and target cells is H–2 restricted and compatibility at the H–2K or H–2D regions of the MHC is essential. But we now have data which indicate that identity at the H–2 complex (or at subregions within this complex) is not required for cytotoxic reactivity between T lymphocytes from mice immunised against murine sarcoma virus (MSV) and tumour-associated antigens on target cells. Spleen cells from immune animals could lyse either syngeneic or allogeneic tumour targets carrying the appropriate tumour-associated antigens. Thus it seems that the antigenic moiety against which the MSV-immune T cell is directed is not exclusively a modification of the H–2 antigen. Furthermore, the magnitude of the cytotoxicity against allogeneic target cells depended on the strain of animal used for immunisation.

BALB/c (H–2^d) or C57BL/6 (H–2^b) mice, 8–12 weeks old, were injected intramuscularly in the leg with a regressor strain of Moloney-MSV. Tumours appeared 7–9 d later, reached maximum size at about 14 d, and then regressed. Spleen cells were collected from the mice 12–14 d after virus inoculation—the peak of cell-mediated cytotoxicity as measured by the ^{51}Cr-release cytotoxicity assay[11,12]—and tested for their cytolytic activity in a 16–18-h ^{51}Cr release assay. The target cells were Rauscher (RLV) or Moloney (MLV) virus-induced lymphomas or chemically induced lymphomas of C57BL/6, BALB/c, A/J or DBA/2 mice (Table 1). These chemically-induced lymphomas were not susceptible to lysis by syngeneic T cells from MSV-immune mice and served as specificity controls.

Spleen cells from both C57BL/6 and BALB/c MSV-immunised mice exhibited strong cytotoxic reactivity against MLV- or RLV-induced syngeneic tumour targets as shown by the representative experiments in Tables 2 and 3. This agrees with previous reports[11,12]. But various levels of cytotoxicity were also observed against allogeneic MLV or RLV tumour target cells, with the strength of the response dependent on the strain of mouse from which effector cells were derived. C57BL/6 spleen cells showed very strong activity against tumour-associated antigens on allogeneic tumour cells. On the other hand, BALB/c effector cells were not as efficient at lysing C57BL/6 tumour targets, for although significant levels of cytotoxicity against allogeneic targets were observed in some cases (Table 2 experiment 1*b*, MBL-2 and experiment 2*b*, RBL-5), reactivity was mostly very low. Cytolysis was specific and not directed against alloantigens (Table 3). MSV-immune B6 effector cells were cytotoxic against syngeneic (H–2^b) and allogeneic (H–2^d or H–2^a) tumour targets but did not lyse allogeneic phytohaemagglutinin (PHA) blasts. Furthermore, there was no lysis against H–2 identical tumour cells which did not carry the appropriate antigen (Table 2 experiments 1*a* and 2*b*) even though these targets could be lysed by alloimmune cytotoxic effector cells (data not shown). When the effector cells were treated with anti-Thy 1.2 antibody plus complement, they could not mediate cytotoxicity, thus confirming the T-cell nature of this immune function (Table 4).

Table 1 Description of lymphoma tumour lines

	Strain of origin	H–2 type	Inducing agent
RBL-5	C57BL/6	H–2^b	RLV

Direct cytotoxic reactivity against tumour-associated antigens on allogeneic tumour cells has not been described before. Herberman *et al.*[13], using a 4-h ^{51}Cr release cytotoxicity assay, saw no cross reactivity against tumour target cells of another strain. But the more sensitive cytotoxicity inhibition assay showed several of the allogeneic tissue culture lines to have

2.5×10^6 spleen cells from animals immunised 12–14 d earlier with MSV were mixed with 1.25×10^4 ^{51}Cr-labelled tumour cells in 35-mm Petri dishes and incubated for 16–18 h at 37 °C on a rocking platform. Supernatants were collected and processed as previously described[12]. Spontaneous ^{51}Cr release was usually 15–35% of the total unless otherwise indicated.

*Percentage specific release of ^{51}Cr (±s.e.) from the tumour cells was calculated according to the formula

$$\frac{\text{c.p.m. supernatant experimental} - \text{c.p.m. supernatant control}}{\text{Total c.p.m. incorporated into cells}} \times 100$$

†$P < 0.01$ as calculated by Student's *t* test compared with control.

detectable levels of antigen[13,14]. On the basis of these inhibition studies, it was concluded that the cytotoxic reactivity of spleen cells from MSV-injected C57BL/6 mice was directed against an endogeneous C-type virus-associated antigen, MEV-SA-1, and even xenogeneic target cells infected with the appropriate virus were found to carry the antigen[15,16]. In contrast, Gomard *et al.*[9] examined the interrelationship between T-lymphocyte cytotoxicity and products of the H–2 complex and concluded that recognition of antigens on the surface of tumour cells by MSV immune T lymphocytes was determined by an H–2 region product. The results of an 18-h ^{51}Cr release assay, however, confirm our previous inhibition data and demonstrate that substantial levels of cytotoxic reactivity can occur against allogeneic tumour cells (especially when effector cells from C57BL/6 MSV-immune mice are used) even though reactivity is still higher and occurs earlier against syngeneic targets (our unpublished observations). Thus in this system we see H–2 preference but not H–2 restriction. Similar observations have been made in virus-infected or hapten-modified systems where some cytotoxic reactivity was also observed against allogeneic modified target cells[17,18].

A further point should be made regarding the specificity of the cytotoxic reactivity. As noted, the antigen recognised on syngeneic tumour cells by C56BL/6 MSV-immune cells is MEV-SA-1. We have not so far identified the antigenic specificity (or specificities) in addition to MEV-SA-1 which can be recognised by these mice on the allogeneic target cells nor have we identified the antigens recognised by BALB/c MSV-immune effector cells. Nevertheless, although the mice were injected with Moloney-MSV, the cytotoxic reactivity against either syngeneic or allogeneic tumour targets did not seem (as suggested[19]) to be associated with a type-specific MLV-induced antigen, for reactivity was observed with each mouse strain against both syngeneic and allogeneic MLV- and RLV-induced lymphomas.

Our findings suggest several models for the control of the specificity of the interaction between tumour-associated antigen and T lymphocytes. First, the tumour-associated antigens induced by the oncogenic viruses in different strains of mice are similar or identical (therefore unrelated to H–2 products) and a receptor on the T lymphocyte for the H–2 of the sensitising cell enables the killer cells to interact more effectively with the target. Such a model would accord with the preference for the syngeneic targets expressed by the MSV effector cells. Second, there are several types of cell surface antigens induced by the virus, with each mouse strain, expressing unique antigens as well as common antigens; in addition, cytotoxic reactivity is stronger against the unique antigens. In such a case, there would have to be at least two subpopulations of effector T cells generated by MSV immunisation, one which reacts predominantly against the unique antigen on syngeneic cells and another which reacts with tumour-associated antigens with allogeneic cells. Third, immune response genes may be controlling the generation of the cell-mediated response and, in such a case, the animal may be able to recognise only some of the antigens induced by the virus. Therefore, although the antigens expressed on the tumour cells may have some common antigenic moieties, the response may be restricted by the ability of the host to recognise that determinant. We cannot distinguish whether one or more of these alternatives are operative in the MSV system.

Table 3 Specificity of the cytotoxic reactivity by MSV-immune lymphocytes in the 18-h ^{51}Cr release assay

Target cells	H–2 type	Effector cells* C57BL/6 ($H-2^b$) MSV immune	C57BL/6 ($H–2^b$) anti-P815 ($H–2^d$)	Baseline‡ release
RBL-5	$H–2^b$	28.7 (2.1)+	0	23.3
MBL-2	$H–2^b$	24.8 (0.7)+	0	43.6

‡Baseline control values were determined using normal thymocytes or non-reactive lymphocytes that gave release values which were below or not significantly different from the thymocyte control.

Table 4 Treatment of MSV-immune effector cells with anti-Thy 1.2 plus complement

C57BL/6 ($H–2^b$) MSV–immune spleen cells	Targets MBL–2 ($H–2^b$)	YC8 ($H–2^d$)
Untreated	33.8 (2.2)	11.3 (1.5)
Media control	34.4 (2.0)	12.5 (1.3)
Complement	34.0 (2.3)	11.2 (1.5)
Anti-Thy 1.2 plus complement	0 (2.3)	-0.9 (1.2)

Spleen cells from C57BL/6 mice immunised with MSV were treated twice according to the following protocol: 10^8 spleen cells were incubated with 0.6 ml of medium or anti-Thy 1.2 (final 1:2 dilution) for 30 min at 22 °C. After one wash the cells were treated with medium or with rabbit complement for 45 min at 37 °C. The cells then were washed twice with medium, resuspended to the same viable cell count, and then assayed for cytotoxicity in the 18-h ^{51}Cr release cytotoxicity assay against two different tumour targets.

Similar to our demonstration of reactivity *in vitro* of immune lymphocytes against syngeneic and allogeneic tumour targets, *in vivo* immunisation procedures with these tumour lines have shown that by immunising with an allogeneic BALB/c lymphoma (LSTRA) C57BL/6 mice could be protected from challenge with a syngeneic tumour (MBL-2)[20]. T lymphocytes have a major *in vivo* role in protection against tumour challenge[21,22] and therefore assuming that the activity detected *in vitro* accurately reflected the events taking place *in vivo*, the cytotoxicity we have observed against BALB/c tumour cells by MSV-immune C57BL/6 lymphocytes might have been anticipated.

We thank Mrs Lena Redmon for technical assistance.

Relationship between β-adrenergic receptors and adenylate cyclase in HeLa cells

THE physiological actions of many hormones and neurotransmitters are mediated through activation of adenylate cyclase (ATP pyrophosphate lyase [cyclising] EC 4.6.1.1) by specific cell surface receptors for each substance. The consequent increases in intracellular cyclic AMP lead to activation of protein kinases and a host of alterations in cell physiology, depending on the type of cell stimulated[1]. Adrenergic receptors, responsive to β-hydroxylated catecholamines, were divided into α- and β-types by Ahlquist[2] using classical pharmacological techniques. The β-adrenergic effects of catecholamines occur through a receptor-mediated stimulation of adenylate cyclase activity[3]. Although β-adrenergic receptors have often been described as 'tightly coupled' to adenylate cyclase, recent evidence suggests that the receptor and the enzyme are physically discrete entities[4,5], probably the products of different genes[6]. We have found that HeLa cells contain β-adrenergic receptors and that the number of receptors per cell, but not the cellular content of adenylate cyclase, increases markedly during exposure of the cell to butyrate[7]. Here we present direct evidence that the HeLa cell β-adrenergic receptor can exist in a form either 'coupled' to or 'uncoupled' from adenylate cyclase. A model system for studies of receptor–adenylate cyclase interactions is described, and preliminary results of studies on the mechanism of coupling are reported.

In previous studies on induction of β-adrenergic receptors by short-chain fatty acids we noted that while 5 mM pentanoic acid was as effective as 5 mM butyric acid for induction of β-receptors as measured by binding of ^{3}H-alprenolol, cyclic AMP production in response to isoproterenol stimulation was only increased about one-third as much by pentanoate as by butyrate[7]. This observation suggested that the specific receptor could be induced in a form which is functionally 'uncoupled' from adenylate cyclase. The total cellular activity of adenylate cyclase did not increase with butyrate treatment; Table 1 shows basal, fluoride-stimulated, and cholera toxin-stimulated adenylate cyclase activities in homogenates of untreated and 5 mM butyrate-treated HeLa cells. The induced receptors apparently become functional by associating with pre-existing adenylate cyclase. As expected, *l*-isoproterenol-stimulated adenylate cyclase activity was higher in homogenates of 5 mM butyrate-treated cells. When induction of receptors was examined as a function of butyrate concentration, we found that while ^{3}H-alprenolol binding was fully induced by low concentrations of butyrate, 10-fold higher concentrations of the fatty acid were required for full expression of *l*-isoproterenol-stimulated cyclic AMP production, as shown in Fig. 1. In general, although higher concentrations of pentanoate were required for induction of binding, at 5 mM the same levels of activity were reached with either fatty acid; pentanoate, however, was far less effective than butyrate in eliciting catecholamine-stimulated cyclic AMP production, in agreement with our earlier observations (data not shown).

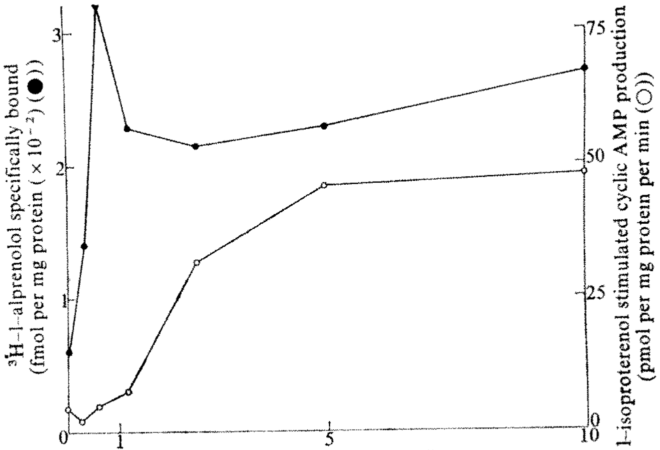

Fig. 1 Effects of various concentrations of butyrate on induction of β-adrenergic receptors and l-isoproterenol-stimulated cyclic AMP production. HeLa cells (Rhino; GIBCO) were grown as previously described[19] in minimal essential medium with non-essential amino acids and 10% foetal calf serum. 150-mm plastic tissue culture dishes were seeded at (3–4) × 10^4 cells cm^{-2} and incubated 24 h at 37 °C. The medium was replaced with fresh medium containing the indicated concentration of butyrate and the incubation continued for an additional 24 h. Dishes were washed with 10 ml phosphate-buffered saline containing 0.2% gelatin (PBS), cells collected by scraping in 10 ml PBS, and collected by centrifugation (3,000 r.p.m. for 4 min at 4 °C). Cells from one 150-mm dish were suspended for assay in 2 ml 0.9% NaCl, 50 mM Tris-HCl (*p*H 7.4) containing 5 mM theophylline and 9 mM 3-isobutyl-*l*-methylxanthine. Specific binding of ^{3}H-dihydroalprenolol and *l*-isoproterenol-stimulated cyclic AMP production were determined as previously described[7].

Time course studies indicated that butyrate induction of ^{3}H-alprenolol binding was complete by 10 h with either 0.5 mM or 5 mM butyrate (ref. 7 for 5 mM, unpublished data for 0.5 mM butyrate); the lower concentration of butyrate induced about 80% of the binding activity induced by the higher concentration. But, 0.5 mM butyrate was far less effective than 5 mM butyrate in eliciting catecholamine-stimulated cyclic AMP production (Table 1). The differential effect of the two butyrate concentrations could not be attributed to slower induction by the lower concentration.

Table 1 Cyclic AMP production in homogenates of HeLa cells after various treatments

Activity measured	Additions to medium None	 0.75 mM butyrate	 5 mM butyrate
	(pmol cyclic AMP produced per min per mg protein)		
Basal*	8.2	9.2	11.4
NaF-stimulated*	135	152	147
Isoproterenol-stimulated*	8.8	22.4	50.6
Cholera toxin-stimulated†	70	ND‡	50

*HeLa cells were incubated 24 h in medium containing the indicated concentrations of butyrate, homogenates prepared, and cyclic AMP determined as previously described[7].

†HeLa cells were incubated for 22 h in medium containing the indicated concentrations of butyrate, cholera toxin was added (4 μg ml^{-1}, 25 ml per dish) and the cells incubated an additional 2 h; homogenates were prepared and cyclic AMP measured as above. In this separate experiment the basal activity of adenylate cyclase (pmol cyclic AMP per min per mg protein) for untreated cells and 5 mM butyrate treated cells were 13.0 and 5.0 respectively.

‡ND, not determined.

An important aspect of the differential effect of the low (0.5 mM) compared with the high (5 mM) butyrate concentration is that it permits us to obtain cells with large numbers of non-functional receptors (Table 1) and, by manipulation of the tissue culture medium contents, to convert them to functional receptors; we will refer to experiments of this type as 'coupling' studies. Additional studies indicated that 0.75 mM butyrate was optimal for maximal differential between binding activity and catecholamine-stimulated cyclic AMP production. After β-receptors were induced by exposing cells to 0.75 mM butyrate, the time course was studied by replacing the initial medium with fresh medium containing 5 mM butyrate. As shown in Fig. 2, coupling begins after a brief lag and increases sharply during the next 6 h. This experimental design was used then to study the effects on coupling of certain inhibitors and medium components.

Table 2 summarises the results of several experiments in which the effects of various inhibitors or omission of certain medium components were examined separately on both the one-step induction of functional receptors and on the coupling of pre-induced receptors with adenylate cyclase. Cycloheximide, at a concentration which we have previously found to inhibit protein synthesis more than 90% in HeLa[8], completely blocked induction of functional receptors when included with 5 mM butyrate during a 24-h incubation. Surprisingly, cycloheximide caused a 90% decrease in pre-induced hormone binding after 24 h in coupling experiments, perhaps suggesting a rapid turnover of receptor molecules. Catecholamine-stimulated cyclic AMP production was less severely suppressed which may indicate that coupling of surviving receptors to adenylate cyclase does not require protein synthesis. Whether or not RNA synthesis is necessary for receptor induction or coupling cannot be determined from the current results (Table 2); our experiments with inhibitors of RNA synthesis apparently suffer from the 'superinduction' ambiguities previously reported[9].

Current models of receptor–adenylate cyclase interactions assume that functional coupling involves physical association of the components of the system and emphasise diffusion of the components in a fluid membrane[4]. Other investigators have suggested that microfilaments are involved in the modulation of certain receptors[10] and that microfilaments may constitute structural bridges between microtubules and cell surface receptors[11]. Our preliminary results with microtubule and microfilament disrupting agents (colchemid and cytochalasin B respectively) do not implicate these subcellular structures in the coupling of β-adrenergic receptors to adenylate cyclase (Table 2). It should be noted, however, that Ash and Singer[12] have shown the involvement of microfilaments in the mobility of concanavalin A receptors but could not demonstrate an effect of cytochalasin B on receptor mobility. Also Resch *et al.*[13] have reported recently that microtubule-disruptive agents do not prevent initiation of lymphocyte activation by concanavalin A binding. Concanavalin A was inhibitory for functional β-receptor induction in HeLa, while stimulating the coupling of pre-induced receptors with adenylate cyclase (Table 2). Concanavalin A binding to lymphocytes has been reported to immobilise many other receptors on the cell surface[12]. In HeLa, concanavalin A binds extensively to the cell surface but does not inhibit ^{3}H-alprenolol binding to β-adrenergic receptors (data not shown). HeLa cells remain viable for more than 24 h when glucose is omitted from the growth medium; in these conditions receptor induction is completely blocked and maintenance of pre-induced receptors is reduced by about half. Production of cyclic AMP in response to isoproterenol stimulation is greatly reduced by the omission of glucose from MEM (Table 2). These effects should be interpreted with caution since glucose-starved cells may be deficient in ATP and NADH (ref. 14). In coupling experiments, the addition of glucose to the cyclic AMP production assay mixture restored the cells' ability to produce cyclic AMP in response to the hormone (data not shown). Omission of Ca^{2+} from the medium was strongly inhibitory for receptor induction, while omission of serum had a less striking but significant effect. In contrast, the omission of either of these medium components had a stimulatory effect in coupling experiments.

These results clearly demonstrate that the β-adrenergic receptor can exist in a state in which it is functionally uncoupled from adenylate cyclase in HeLa cells. Exposure of cells to butyrate induces a striking increase in isoproterenol-stimulated adenylate cyclase activity. When high concentrations

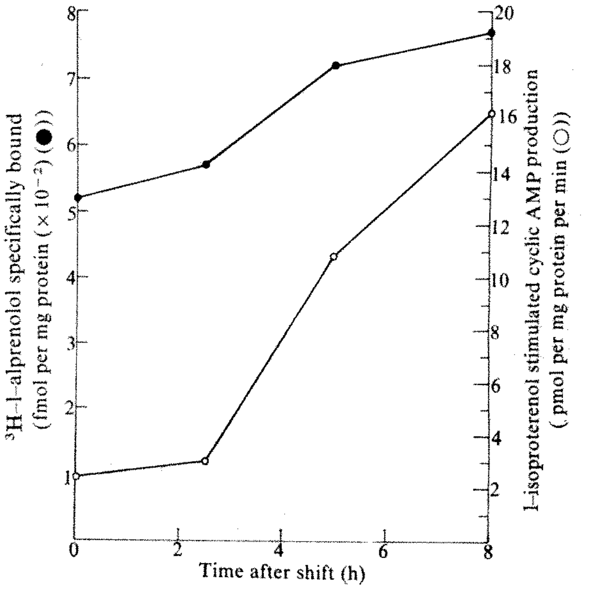

Fig. 2 Coupling of pre-induced β-adrenergic receptors with pre-existing adenylate cyclase. HeLa cells were cultured and collected and specific ^{3}H-dihydroalprenolol and *l*-isoproterenol-stimulated cyclic AMP production determined as described in the legend to Fig. 1. Cells were incubated in medium containing 0.75 mM butyrate for 20 h and transferred to fresh medium containing 5 mM butyrate at zero time.

Table 2 Effects of inhibitors and/or omission of medium components on β-adrenergic receptor induction and coupling to adenylate cyclase

Addition/omission to medium+5 mM butyrate	Induction of functional β-receptors		Coupling of β-receptors and adenylate cyclase	
	^{3}H-dihydroalprenolol bound (%)	Iso-stimulated cyclic AMP (%)	^{3}H-dihydroalprenolol bound (%)	Iso-stimulated cyclic AMP (%)
None	100	100	100	100
+ Cycloheximide (20 μg ml^{-1})	14	<2	12	41
+ Actinomycin D (1 μg ml^{-1})	55	212	31	152
+ Cordycepin (10 μg ml^{-1})	249	139	ND	ND
+ Colchemid (1 μg ml^{-1})	91	91	101	98
+ Cytochalasin B (1 μg ml^{-1})	84	91	124	126
+ Concanavalin A (25 μg ml^{-1})	43	46	144	204
− Glucose	<1	<1	39	<1
− Ca^{2+}	<1	29	164	188
− Serum	56	53	281	127

For induction of functional β-receptors, HeLa cells were incubated for 24 h in medium, the medium replaced with medium containing 5 mM butyrate and the indicated addition or omission, incubation continued for 20 h and the cells collected. For coupling studies, cells were incubated 24 h in medium and the medium replaced with medium containing 0.75 mM butyrate; after 20 h incubation this was replaced with medium containing 5 mM butyrate, incubation continued for an additional 20 h and cells collected. ^{3}H-dihydroalprenolol binding and isoproterenol-stimulated cyclic AMP production were determined as before[7]. ND, Not determined.

(>2 mM) of butyrate are used, β-receptors are induced and become functionally coupled with pre-existing adenylate cyclase molecules within 10 h. At lower concentrations of the fatty acid, the receptors increase in number but do not become functionally coupled with the enzyme; a subsequent shift to the higher butyrate concentration leads to the onset of coupling after a brief lag. This system may prove useful for the study of receptor–adenylate cyclase interactions.

The effects of short-chain fatty acids on HeLa and other mammalian cells in culture are manifold. Among the phenomena elicited by the exposure of cells to butyrate are the following: (1) The inhibition of growth and alteration of morphology in HeLa[15], Chinese hamster ovary[16], and neuroblastoma cells[17]. (2) Increases in the ganglioside G_{M3} and its biosynthetic enzyme in HeLa[18–20]. (3) Increase in alkaline phosphatase activity in HeLa[21]. (4) Increased synthesis of the β-subunit of human chorionic gonadotropin in HeLa[22]. (5) Induction of erythroid differentiation in erythroleukaemic cells[23]. (6) Induction of tyrosine hydroxylase and acetylcholinesterase activity in mouse neuroblastoma cells[17]. And (7) shape change correlated with elaboration of microfilaments and microtubules in transformed rat kidney cells[24].

In this report we have described at least two separate effects in HeLa cells: induction of β-receptor synthesis by low concentrations of butyrate and stimulation of receptor–adenylate cyclase coupling by higher concentrations.

Thyroid hormone controls glucocorticoid action in cultured GH_1 cells

WE have demonstrated that L-triiodothyronine (T3) stimulates growth hormone synthesis three to four-fold[1–3] and inhibits prolactin secretion[1] in cultured GH_1 cells, which constitute a rat pituitary cell line. Others have shown that cortisol also stimulates growth hormone production in GH_1 cells[4]. In GH_3 cells, a closely related cell line, cortisol stimulates growth hormone production four- to eightfold and inhibits prolactin secretion approximately fourfold[5]. Thus, thyroid and glucocorticoid hormones seem to control similar growth hormone and prolactin responses in GH_1 and GH_3 cells. Studies of the effects of glucocorticoids in these cell lines[4,5], however, have used commercial serum preparations containing physiological concentrations of thyroid hormone[6]. To examine the intrinsic response of these cells to glucocorticoid, therefore, it is necessary to use medium supplemented with serum which contains very low thyroid hormone levels. Using culture medium supplemented with hypothyroid calf serum, we have examined the influence of T3 and cortisol on the induction of growth hormone synthesis in GH_1 cells. We report here that in the absence of T3, the cells seem unresponsive to glucocorticoids, whereas in its presence cortisol markedly enhanced growth hormone production. The apparent requirement of T3 for expression of the cortisol response seems independent of any influence of T3 on total cell steroid receptor levels or the nuclear-cytoplasmic distribution of the steroid receptor, and of any effect of cortisol in modulating the level of the T3 nuclear receptor.

Figure 1 illustrates a T3 dose–response study for growth hormone production determined by radioimmunoassay with and without 100 nM cortisol after a 20-h incubation. At this time the cellular response to T3 is maximal[2]. T3 alone stimulated a 7.5-fold increase, with a half-maximal response induced by 0.3 nM T3. This is essentially the same as the value we obtained by quantifying directly the rate of synthesis using ^{35}S-methionine followed by immunoprecipitation of the intracellular labelled growth hormone[3]. At each concentration of T3, 100 nM cortisol resulted in a twofold increase in growth hormone production with a half-maximal response also at 0.3 nM T3. Cortisol therefore seems to potentiate the action of T3 without altering the

T3 dose–response characteristics. In both cases, the biological dose–response relationships are in excellent agreement with the concentration of T3 (0.3 nM) that results in half-maximal occupancy of the thyroid hormone nuclear receptor in GH_1 cells[3]. This suggests that the T3–nuclear receptor complex controls a rate limiting event in the induction of growth hormone synthesis and that cortisol enhances the response initiated by T3.

Figure 2 illustrates a dose–response curve for growth hormone production as a function of cortisol concentration in the absence of T3 and in the presence of 0.3 nM and 5 nM T3, which respectively give half-maximal and full induction. Without added cortisol, the rate of growth hormone production induced by the two T3 concentrations is identical to that in the dose–response curve in Fig. 1. In the absence of T3, cortisol up to 5 μM resulted in no increase in growth hormone production. With 5 nM T3, growth hormone production was maximal with 100 nM cortisol, and decreased slightly with higher steroid concentrations, probably due to a reduction in rates of synthesis of cell protein[4,5]. At each T3 concentration, there was a half-maximal increase in growth hormone production at 18 nM cortisol, which agrees with the cortisol dose–response curve for tyrosine aminotransferase reported for hepatoma tissue culture (HTC) cells[7]. The regulation of enzyme induction by glucocorticoids in HTC cells is mediated by steroid binding to a cytosol receptor[8], followed by translocation of the steroid–receptor complex to the nucleus[9,10]. Based on the dose–response studies of the growth hormone response, it seems likely that cortisol acts by a similar steroid receptor mechanism and in some way potentiates the action of T3 which functions as the primary inducer.

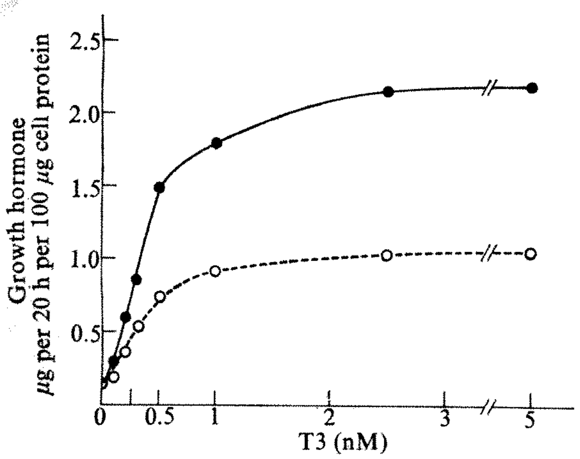

Fig. 1 Influence of cortisol on the induction of growth hormone production by T3. GH_1 cells were grown using Ham's F-10 medium supplemented with 2.5% foetal calf serum and 15% horse serum as previously described[2,3,6]. The cells (150,000) were inoculated into wells of a 24-position Falcon multiwell plate, each with a surface area of 2 cm². After 48 h at 37 °C, the medium was exchanged with Ham's F-10 medium containing 10% hypothyroid calf serum and the cells were incubated for a further 48 h. The medium was then replaced with Ham's F-10 medium containing 10% hypothyroid calf serum and T3 was added at the concentrations indicated with (●) and without (○) 100 nM cortisol. The cell cultures were incubated for a further 20 h and growth hormone was quantified in the medium by radioimmunoassay[1]. Because T3 (ref. 2) and glucocorticoids[5] have no effect on the intracellular or extracellular degradation of growth hormone, and the intracellular pools are extremely low, the level of growth hormone determined in the medium by radioimmunoassay is an indirect measurement of rates of synthesis of growth hormone during incubation[2,5]. After the medium was removed, each well was washed three times with 0.14 M NaCl at 4 °C and total cell protein was determined by the method of Lowry *et al.*[22]. Rates of production of growth hormone are expressed as μg of growth hormone produced per 20 h per 100 μg of cell protein. Each well contained approximately 60 μg of cell protein.

This is supported by studies using an anti-glucocorticoid in GH_1 cells. Samuels and Tomkins[7] identified several compounds (anti-inducers) which did not induce tyrosine aminotransferase in HTC cells but competitively inhibited the induction of the enzyme by cortisol. These findings were interpreted in terms of the interaction of these steroids with an allosteric receptor system concerned with induction of the enzyme. Two of these compounds, 17α-methyltestosterone (17αMeT) and progesterone, seem to act by inhibiting the binding of glucocorticoid to its receptor[8], and evidence indicates that anti-inducers modify mRNA accumulation[11-13]. Table 1 illustrates the effect of the anti-inducer 17αMeT on the growth hormone response induced by T3 and by T3 plus cortisol. The growth hormone response was assessed in separate experiments using radioimmunoassay[1] to measure total hormone production, and by incubating cells with ^{35}S-methionine for 15 min followed by immunoprecipitation to quantify relative rates of synthesis[2,3]. By either method, neither cortisol nor 17αMeT alone or in combination, stimulated growth hormone synthesis. In each case, T3 stimulated an increase in the growth hormone response and this was stimulated threefold further by 100 nM cortisol. 17αMeT decreased the growth hormone response in the cells incubated with T3 and cortisol to that of T3 alone, and only minimally influenced the response induced by T3 alone. Rates of synthesis of total cell protein were similar in all cases, with the exception of a slight reduction with cortisol alone or T3 plus cortisol, which is consistent with previous reports[4,5]. These results support the concept that T3 is the primary inducer of growth hormone synthesis and cortisol potentiates the T3 response by a mechanism which involves the glucocorticoid receptor.

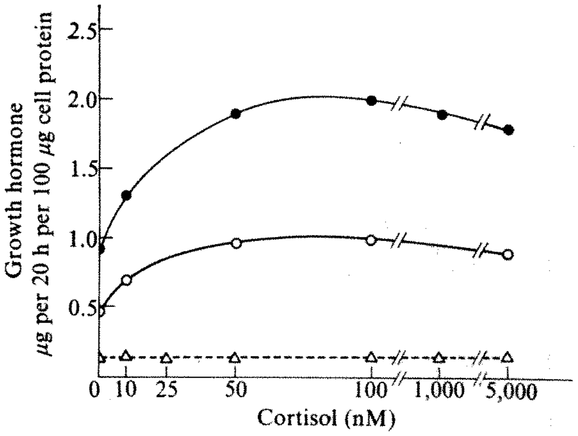

Fig. 2 Influence of T3 on cortisol induction of growth hormone production. The experiment was the same as in Fig. 1 except that the cells were incubated with cortisol without T3 (△), with 0.3 nM T3 (○) and with 5 nM T3 (●).

Growth hormone induction by T3 seems to be initiated by the association of T3 with a receptor localised in the cell nucleus[2,3,14], and seems to be explained by the accumulation of growth hormone mRNA[2]. After 24 h, 5 nM T3 results in reduction of the thyroid hormone nuclear receptor to 40% of the initial value[3]. Therefore, the potentiation by cortisol of the response to T3 might be due to prevention of T3-mediated reduction of the thyroid hormone nuclear receptors resulting in an enhanced cellular response to T3. Stimulation of growth hormone synthesis by cortisol plus T3 might also be due to a T3-mediated increase of the glucocorticoid receptors.

Table 2 shows investigation of these possibilities. As before[3], 5 nM T3 resulted in a 40% reduction in its homologous nuclear receptor population. Cortisol did not prevent receptor depletion by T3, and therefore the potentiation by cortisol of the response to T3 cannot be explained by interference in the reduction of the thyroid hormone receptor by T3.

T3 also had no effect on the level of the total glucocorticoid receptor or the nuclear-cytoplasmic distribution of the steroid

Table 1 Influence of T3, cortisol and 17αMeT on synthesis of growth hormone

Additions	Growth hormone production (radioimmunoassay, μg per 100 μg cell protein per 20 h)	Growth hormone synthesis (c.p.m. per 100 μg DNA $\times 10^{-2}$)	Total cell protein synthesis (c.p.m. per 100 μg DNA $\times 10^{-4}$)
None	0.56	688	1,051
Cortisol, 100 nM	0.50	617	800
17αMeT, 10 μM	0.48	700	1,200
Cortisol, 100 nM plus 17αMeT, 10 μM	0.49	720	1,125
T3, 5 nM	2.60	1,502	1,100
T3, 5 nM plus 17αMeT, 10 μM	2.10	1,252	1,190
T3, 5 nM plus cortisol 100 nM	7.00	3,924	960
T3, 5 nM plus cortisol, 100 nM plus 17αMeT, 10 μM	2.50	1,304	1,132

The protocol was as described in the legend to Fig. 1. Additions were as indicated. The cells were incubated for 20 h and growth hormone production was determined by radioimmunoassay of the growth hormone content of the medium. Rates of synthesis of growth hormone were estimated in a separate experiment using the same protocol as in Fig. 1, except that 1×10^6 cells were initially inoculated into 25-cm^2 Falcon T flasks[3]. After incubation for 24 h at 37 °C with compounds indicated, the cells were incubated with ^{35}S-methionine (50 μCi ml^{-1}, 635 Ci mmol^{-1}) for 15 min. Total cell protein synthesis, and growth hormone synthesis quantified by specific immunoprecipitation of intracellular labelled growth hormone, was measured as before[2,3]. Cell DNA content was determined by the method of Burton[23] and cell protein by the method of Lowry *et al.*[22]. Each point represents the mean of three determinations and each sample did not vary more than 5% from the mean.

receptor. The estimated level of glucocorticoid receptor binding sites per cell (approximately 12,000) agrees with the values reported for other cell systems[15]. The percentage of total glucocorticoid receptor identified in the nucleus, however, is approximately half of that reported for most other cell systems but is identical to that determined in glucocorticoid-sensitive lymphoma cells[16]. Therefore, the potentiation by cortisol of the response to T3 is not explained by one hormone modulating the receptor level of the other. It is possible, however, that T3 modifies a biologically relevant subset of nuclear association sites for the glucocorticoid receptor and that this is not identified by measuring the total nuclear associated glucocorticoid receptor.

Evidence indicates that glucocorticoids act at the pretranslational level to increase the rate of accumulation of mRNA[11–13,17,18]. When medium was used which was not devoid of thyroid hormone, glucocorticoids induced a concomitant increase in growth hormone production and growth hormone mRNA in GC cells, a cell line closely related to GH$_1$ cells[19,20]. This suggests that the enhancement by cortisol of the response of GH$_1$ cells to T3 occurs at a level proximal to translation. Therefore, GH$_1$ cells provide a system for the examination of the initiation and potentiation of a specific response which seems to be regulated at the level of the cell nucleus. Because glucocorticoids induce tyrosine aminotransferase in HTC cells in serum-free conditions, thyroid hormone does not seem to be important for steroid action in HTC cells[7,21]. Whether our observations with GH$_1$ cells of the interrelationship between thyroid hormone and glucocorticoid apply to other systems responsive to these hormones remains to be examined.

Table 2 Quantitfication of T3 and glucocorticoid receptors in GH$_1$ cells

Incubation	Nuclear T3 receptors (fmol per 100 μg DNA)	T3 receptor binding sites per nucleus	Glucocorticoid receptors (fmol per 100 μg DNA) Cytoplasm	Nuclei	Glucocorticoid receptor binding sites per cell
Control	180	17,800	121	35.9	12,200
T3, 5 nM	110	10,877	121	34.9	12,100
T3, 5 nM plus cortisol, 100 nM	100	9,888	—	—	—

The protocol was as described in the legend to Fig. 1 except that 3×10^6 GH$_1$ cells were inoculated into 75-cm^2 Falcon T flasks. After incubation of cells in the presence of medium containing 10% hypothyroid calf serum for 48 h, either 5 nM ^{125}I-T3 or 5 nM ^{125}I-T3 plus 100 nM of non-radioactive cortisol was added for 24 h while a parallel set of flasks served as controls. One hour before the cells were collected, 5 nM ^{125}I-T3 was added to control flasks to determine the level of receptor present in cells not exposed to T3 during the 24 h (ref. 3). The T3 bound to nuclei was determined as before[3,14]. The magnitude of nonspecific binding was determined by simultaneous incubation with a 500-fold molar excess of non-radioactive T3. This value represents less than 5% of the total T3 bound[3] and was subtracted from the total to give the values above. DNA was quantified by the method of Burton[23]. In other flasks, cells were incubated with 5 nM non-radioactive T3, while a parallel group of flasks served as controls. Glucocorticoid receptor levels were then determined by incubating GH$_1$ cells with 100 nM ^{3}H-cortisol (91 Ci mmol^{-1}) with and without a 500-fold molar excess of non-radioactive cortisol for 1.25 h at 37 °C. (ref. 24). The flasks were chilled by partially submerging them in ice for 15 min and the cell monolayers were rinsed three times with 10 ml of 4 °C 0.14 M NaCl. All further procedures were carried out between 0 and 4 °C. The cells were homogenised in buffer containing 0.25 M sucrose–20 mM Tris-HCl–1.1 mM $MgCl_2$ (*p*H 7.6 at 25 °C)[14] and the samples were centrifuged at 800*g* for 10 min and nuclei were prepared from the resultant pellets with Triton X-100 as before[3,14]. Purified nuclei were dissolved in 0.4 ml of 0.4 N NaOH and the ^{3}H-cortisol bound was determined with a liquid scintillation counter using Aquasol solution. The labelled cortisol bound in the cytoplasmic fraction was determined by incubating triplicate 1-ml fractions with 2 mg of Norit A charcoal and 0.2 mg of Dextran (Sigma, molecular weight 500,000) for 2 min followed by centrifugation at 2,000*g* for 5 min (ref. 24). The derived supernatant fractions were analysed for labelled cortisol binding after the samples had been dissolved in Aquasol. ^{3}H-cortisol binding to the nucleus or cytoplasmic fraction, bound to receptor, was calculated by subtracting the total labelled cortisol bound from that determined in the presence of a 500-fold molar excess of non-radioactive cortisol. These results represent the mean of a triplicate determination and each sample did not vary more than 8% from the mean. DNA was determined[23] on the nuclear fraction and the results are expressed as fmol bound per 100 μg of DNA. The number of receptor binding sites per cell was based on the fact that 1×10^6 cells contain 13 μg of DNA (ref. 14).

Muscarinic antagonists block cone to horizontal cell transmission in turtle retina

As in other vertebrate retinas, the cone photoreceptor cells of the turtle are connected by complex synaptic endings with both horizontal and bipolar cells[1]. The cone endings release their transmitter continuously in the dark, and light stimulation suppresses this release[2–7]. The exact nature of the synaptic transmitter released by the cones is unknown but it is known to depolarise the horizontal cells[5,8]; to depolarise the 'hyperpolarising' bipolar cells[5,6] and to hyperpolarise the depolarising bipolar cells[5,6]. It can also be foreseen that any interference with either the release or the postsynaptic action of this transmitter will cause an hyperpolarisation of both the horizontal and the hyperpolarising bipolar cells and a depolarisation of the depolarising bipolar cells, as well as the block of the light responses of the three cell types. Lam[9] has shown that isolated cones of the turtle retina incubated in the presence of labelled precursors of acetylcholine (ACh) were able to synthesise ACh. In other species, however, assays of choline acetyltransferase activity in different layers of the retina showed a relatively low concentration of the enzyme in the outer plexiform layer (see ref. 10 for review) and ACh application to horizontal cells had no appreciable effects in carp and gekko retinas[11]. Yazulla and Schmidt[12] recently reported that binding sites for ^{125}I-labelled α-bungarotoxin (a snake venom which specifically binds to ACh nicotinic receptors) can be demonstrated by autoradiography in the retina of goldfish and turtle and that the majority of these binding sites are located in the outer plexiform layer. In an attempt to re-evaluate the possibility that ACh is the neurotransmitter liberated by cones, we studied the effects of some ACh agonists and antagonists on the cone to horizontal cell transmission. Our most interesting finding is that agents known to block the ACh muscarinic receptors block preferentially, and very probably at the post synaptic level, the synaptic transmission from the cone to the horizontal cell. Moreover, the same agents do not block the transmission from the cone to the hyperpolarising bipolar cells.

The eye was removed from the turtle, *Pseudemys scripta*, cut obliquely behind the iris and the vitreous fluid was drained. The eye cup was then mounted and fixed in a suitable chamber and perfused during the whole experiment with a bicarbonate–Ringer solution[13] (4–5 ml per min, 110 mM NaCl, 2.6 mM KCl, 2 mM $MgCl_2$, 22 mM $NaHCO_3$, 2 mM $CaCl_2$, 10 mM D-glucose) continuously bubbled with a 95% O_2+5% mixture, so as to be kept at *p*H 7.8. The drugs used were dissolved in the Ringer solution and applied to the retina through the perfusing system through a multi-way tap. Intracellular recordings were performed using single high resistance micropipettes (300–600 MΩ) filled with 4 M potassium acetate. The retina was stimulated with a double beam photostimulator, the light stimuli were images of circular apertures 50–3,600 μm in diameter. The light sources were tungsten lamps, and neutral density filters were used to reduce their intensity. The total flux density of unattenuated light at the retinal level was 6×10^3 μW cm^{-2} with wavelengths of 400–800 nm.

Retinas are very rich in acetylcholinesterase, particularly in the inner layers[10], so we thought it very unlikely that ACh could reach the outer plexiform layer without being hydrolysed. We therefore applied carbachol (an ACh analogue not hydrolysed by the esterase) to the retina and studied its effects on the L-horizontal cells. The membrane potential of L-horizontal cells varies between two extreme levels, a dark potential level and a light potential level; carbachol at high concentrations (1–5 mM) causes a depolarising shift of both the dark and light membrane potential levels, thus markedly decreasing the light responses of L-horizontal cells. This effect was reversible and disappeared after washing, but this action of carbachol was not observed in all experiments.

In spite of the irregularity of the action of this agonist, we pursued our pharmacological study by applying to the L-horizontal cells a series of ACh antagonists. The nicotinic antagonists, gallamine (flaxedil), hexamethonium and tetraethylammonium in concentrations up to 5 mM and tubocurarine at up to 1 mM neither altered the dark potential nor reduced the light responses of the horizontal cells. The muscarinic antagonists, in contrast to the nicotinic antagonists, showed a consistent blocking action. As seen in Fig. 1, application of atropine (1–5 mM) caused a progressive hyperpolarisation and, in parallel, a marked and progressive reduction of the light responses (Fig. 1*c*). Atropine also slowed down the hyperpolarising phase of the responses and caused the appearance of a small off-depolarisation (Fig. 1*d*). The responses became almost completely blocked after 15–20 min of atropine perfusion (Fig. 1*c*, *d*). The action of atropine could be reversed, but only by prolonged washing. Effects similar to those produced by atropine were produced by other muscarinic antagonists such as hyoscine and probanthine, but their blocking efficacy was lower at similar dose ranges.

The effect of other ACh agonists on L-horizontal cells was also studied. The nicotinic agonist, decamethonium (5 mM), was inactive. The muscarinic agonist, pilocarpine (1 mM), depolarised the L-horizontal cell membrane potential and reduced the amplitude of the light responses, and at higher doses, produced a mixture of antagonistic and agonistic effects. Amongst the other muscarinic agonists tested, arecoline (1–5 mM) behaved as an antagonist, blocking the responses as atropine does, and acetyl-β-methylcholine was completely ineffective.

We also explored the action of anticholinesterase agents on the L-horizontal cells. Eserine (2–5 mM) caused a depolarising shift of the dark potential which was followed by a hyperpolarisation. This latter phase was accompanied by a marked decrease of the light response, the development of a large off-depolarisation and a marked depolarising shift of the membrane potential level in the light. Analogous but milder effects were produced by similar concentrations of neostigmine and edrophonium.

The data relating to the action of atropine and other muscarinic antagonists deserve a more detailed analysis. Thus atropine was found to show some presynaptic action, since it caused both a slight hyperpolarisation of the cones (Fig. 1*a*, *b*) and a reduction of their response to light. But, the effect of atropine on the L-horizontal cells cannot be explained by this presynaptic effect alone: Fig. 1 shows that atropine reduced the cone response by at most one-third of its original amplitude, whereas the L-horizontal cell response was almost completely suppressed.

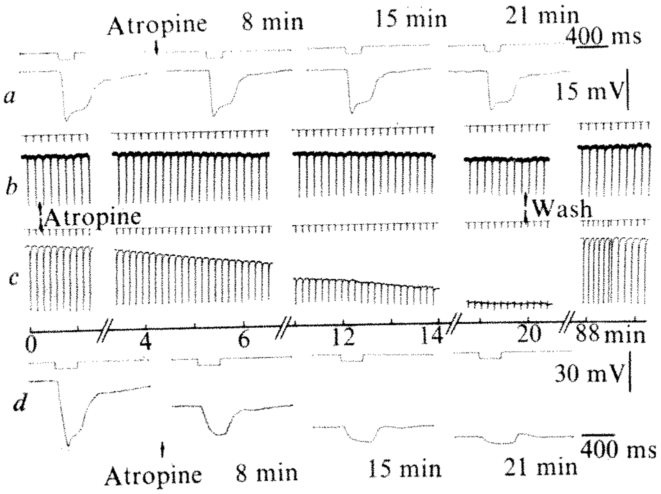

Fig. 1 Intracellular recordings from a cone (*a*, *b*) and from an L-horizontal cell (*c*, *d*) of turtle retina. The trace above each recording gives the timing of the light stimulations. Both cells were stimulated with white light (relative intensity, −1.3), the cone with a 155 μm diameter light spot whereas the spot used for the horizontal cell had a diameter of 3,600 μm. The low speed recordings in (*b*) and (*c*) have a common time base as shown below the (*c*) trace. Application of atropine 5 mM (arrows) caused in the cone (*b*) a slight hyperpolarisation and reduction of amplitude of the light response, which became diminished by one-third. In (*c*), atropine produced a hyperpolarisation of the L-horizontal cell and almost blocked the light response. After recordings (*b*) and (*c*) prolonged washing resulted in a recovery of the response of both cells. *a* and *d* correspond respectively to high speed recordings from a cone and L-horizontal cell. The light responses of both cells were recorded (from left to right) just before, and after 8, 15 and 21 min of atropine application. Note that in (*d*) the almost complete block of the horizontal cell light response and the development of an off-depolarisation.

Moreover, and more importantly, atropine was found to have little effect both on the dark potential and on the response of the hyperpolarising bipolar cells to light spots which stimulated the centre of their receptor field (that is, which activated the direct connection between the cone and the bipolar cell). This observation was confirmed in 10 different hyperpolarising bipolar cells (recognised as such by the criteria set by Schwartz[14] and Richter and Simon[15]). Figure 2*a* corresponds to a typical response of one of these bipolar cells in response to a central light spot, showing both the membrane noise decrease during the hyperpolarisation and an off-depolarisation. The response of Fig. 2*b* was recorded from the same cell after more than 25 min of atropine application, and it is evident that the response was only slightly reduced, and that the membrane noise was not altered, the small reduction of the light response amplitude being probably a consequence of the aforementioned diminution of the cone response (moreover, in two cases we observed an actual increase of the bipolar response under atropine). We conclude from this experiment that atropine does not affect the connection between the cones and the hyperpolarising bipolar cells, and therefore the effect of the drug on the L-horizontal cells cannot be presynaptic. If the transmitter release from the cones were actually decreased, the bipolar cells would have been hyperpolarised, and both a decrease of the membrane noise in the dark and a block of their hyperpolarising responses would have been observed.

From the results presented here we conclude that atropine and other muscarinic agents block the cone to L-type horizontal cell synapses by acting mainly at the postsynaptic level. It is difficult, at this stage, to relate these results to a possible transmitter role of ACh in the cone synapses. The effective concentrations of the agonists and antagonists used were very high, and we do not know if the need for such high concentrations is due to the existence of diffusion barriers or because we are dealing with nonspecific effects of muscarinic drugs which only appear at high doses. Diffusion barrier mechanisms would also account for the irregularity of effect of some of the choline derivatives as seen by us and by other workers.

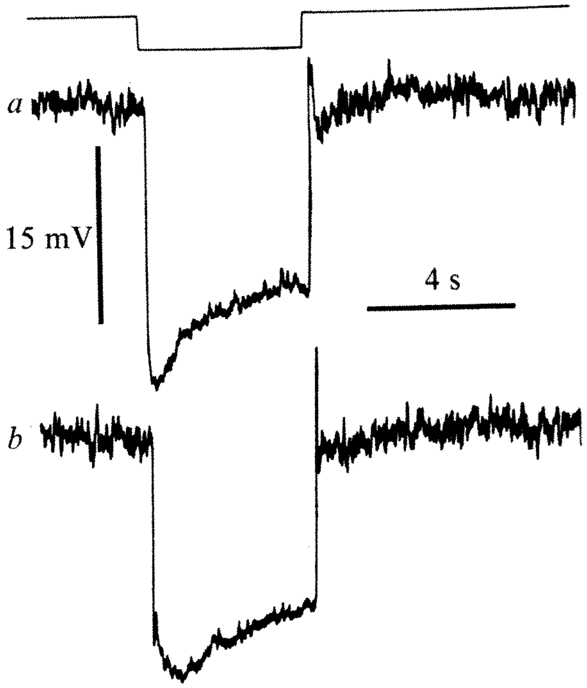

Fig. 2 *a*, Control hyperpolarising response of a hyperpolarising bipolar cell to the stimulation of the centre of its receptor field with a white light spot (diameter 600 μm, relative intensity −2.3). Note the reduction of the membrane noise during the hyperpolarisation. *b*, Response from the same cell to an analogous stimulation, recorded after applying atropine 5 mM to the preparation for 25 min. The response was slightly decreased in amplitude but no alteration in membrane noise was observed.

Finally, it is interesting to note that if ACh were the transmitter released from the cones our results imply that it should act on different receptors on the L-horizontal cells and on the hyperpolarising bipolar cells.

The main finding which we want to emphasise is that atropine blocks preferentially the synaptic responses of L-horizontal cells at the postsynaptic level. In the following paper[16] this property of atropine is used to analyse some of the known lateral cell interactions in the outer plexiform layer of the turtle retina.

Lateral interactions in the outer plexiform layer of turtle retinas after atropine block of horizontal cells

IN the retina of the turtle and of other vertebrates, L-type horizontal cells are thought to play an interneuronal role ensuring long-distance linking between other retinal cells which synapse in the outer plexiform layer. L-type horizontal cells have been thus implicated in: (1) the feed-back loop through which peripheral stimulation evokes a depolarising synaptic potential in cones[1-3], (2) the cell network which participates in the generation of responses of opposite polarity in chromatic C-type horizontal cells[2,4,5] and (3) in the centre surround organisation of bipolar cells, where horizontal cells have been postulated to mediate the responses to peripheral stimulation[6-8]. We have shown previously[9] that atropine and other muscarinic antagonists block the cone to L-horizontal cell transmission, but do not block the cone to hyperpolarising bipolar cell transmission. Taking advantage of this pharmacological distinction, we investigated the participation of the L-horizontal cells in the above mentioned cases of lateral interaction at the outer plexiform layer. We found that atropine blocks both the feedback depolarising potential of the cones and the responses of the C-type horizontal cells, having eliminated previously to this block the opposition between the responses to different colours. At variance with these blocking actions, atropine does not block, and even increases, the depolarising surround responses of the hyperpolarising bipolar cells. These findings confirm the conclusions of previous authors that L-type horizontal cells are involved in generating both the feed back depolarising potential in the cone and the opposite responses of C-type horizontal cells to different colours. Contrary to current ideas, they demonstrate that the L-horizontal cells are not responsible for the depolarising responses of the hyperpolarising bipolar cells to the stimulation of the periphery of their receptor field.

The preparation and the general experimental procedures were similar to those described previously[9]. Atropine was used in these experiments at 5 mM. The retina was stimulated with concentric circular and annular stimuli of white or monochromatic light using apertures varying between 50 and 3600 µm in external diameter, presented either alternately or simultaneously.

Figure 1 corresponds to one of a series of experiments on the cone feedback mechanism. The recordings of Fig. 1 were obtained from a cone responding to central spot illumination with a typical 15-mV amplitude hyperpolarisation (Fig. 1*a*) and which responded to a very bright annular flash with a fast hyperpolarisation (Fig. 1*b*). The stimulation of this cone by a combination of both spot and annulus in appropriate timing (Fig. 1*c*), resulted in the appearance of a depolarising feedback potential with the characteristics described by Baylor *et al.*[1]. After bathing the retina in atropine for 15–20 min, the feedback depolarising potential of the cones disappeared completely and the annular stimuli then only evoked a small hyperpolarisation (Fig. 1*f*). It is well known that the feedback depolarisation is rather labile and that, in many cases, it may disappear spontaneously. At least in four cones studied (among them, the one recorded in Fig. 1) it was possible to observe a complete recovery of the feedback potential after removal of the atropine. These experiments on the feedback depolarising potentials confirm the existing evidence[2] on a L-horizontal cell participation in these responses.

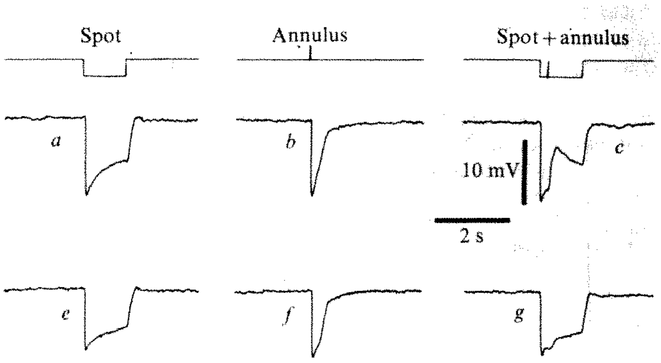

Fig. 1 Atropine effect on the feedback depolarising potential of a turtle cone. The top row of traces shows the timing and duration of the light stimuli. *a–c*, Control recordings in a cone. In (*a*) the cone responds with an hyperpolarisation to a centred spot of white light (diameter 250 µm, relative intensity −2.3). In (*b*) the same cone was stimulated with a bright annulus (internal diameter 430 µm, external diameter 3,600 µm; relative intensity −0.3) which caused a fast hyperpolarisation (which probably resulted from light scattering to the centre). The recording in (*c*) shows the appearance of a feedback depolarising potential when the annulus is presented during the centre stimulation, 180 ms after the onset of the latter. The recordings (*d–f*) were obtained from the same cone, using the same stimulation parameters, after perfusing the preparation with atropine 5 mM. Note that in (*f*) the depolarising feedback potential has been blocked and that flashing of the annulus in the same temporal relation with the centre stimulation only evokes a small hyperpolarisation due to light scattering.

Another lateral interaction mechanism in which the atropine blocking experiments support the idea of a participation of L-horizontal cells, concerns the organisation of the colour responses of the C-type horizontal cells. Figure 2 shows recordings from a green–red coded C-type horizontal cell which was alternately stimulated with large spots of red and white light. White flashes resulted in an hyperpolarisation, while red (650 nm) flashes depolarised the cell (Fig. 2*a*). Application of atropine to the preparation caused a slowly developing hyperpolarisation of the C-type horizontal cell and a decrease in the amplitude of both kinds of responses, although in the first minutes the hyperpolarising responses decreased faster than depolarising ones. After 8 min of atropine application (Fig. 2*b*) both responses were equally diminished but it could be seen that the responses to red flashes became biphasic, the depolarisation appearing then preceded by a short hyperpolarisation. Progressive blocking of the C-horizontal cells was accompanied by a reversal of the responses to red stimuli, and Fig. 2*c* shows that after 15 min of atropine perfusion both types of stimuli evoked very small hyperpolarisations. The atropine-induced reversal of the responses to red flashes can be interpreted by assuming that in normal conditions the depolarising red response masks a direct hyperpolarising response due to stimulation of the green cones, which reappears when L-horizontal cells are blocked. This finding is consistent with the interpretation[5] that the opposite responses of the red–green coded C-type horizontal cells involve L-horizontal cells interconnecting red and green cones.

The last problem of lateral interaction which we analysed with the aid of atropine is probably the most interesting one and concerns the organisation of the receptor field of the hyperpolarising bipolar cells. Figure 3 shows at left, a series of intracellular recordings from a hyperpolarising bipolar cell identified (as the group of ten we studied) by[8,10]: (1) the high sensitivity to dim light, (2) the centre-surround organisation, (3) the typical off-depolarisation after prolonged stimuli and (4), the attenuation of the membrane noise during light centre response[11]. In the experiment of Fig. 3, the hyperpolarising bipolar cell responded by a 20 mV hyperpolarisation to a centrally located spot stimulus and by a few mV depolarisation to a concentric annular flash (Fig. 3*a*). The recordings on the right side of Fig. 3 (*d, e*) were obtained from L-horizontal cells in the same preparation. The right top recording (Fig. 3*d*) is from an horizontal cell recorded before finding the bipolar cell at left and which was stimulated with a large spot with the same illumination intensity parameters used for centre stimulation of the bipolar cell. The recording of Fig. 3*e* is from one of a group of L-horizontal cells penetrated immediately after removing the pipette from the bipolar cell (that is, after an exposure of the preparation to atropine for more than 20 min). As described in the previous paper, the hyperpolarising responses of the hyperpolarising bipolar cells to a central light spot were only slightly reduced after atropine application (Fig. 3, middle and bottom left recordings), and developed complex off-phases. Moreover, the depolarising responses to peripheral stimuli were not blocked, but even increased after 20 min of atropine application (Fig. 3*c*). This observation was repeated on 10 hyperpolarising bipolar cells and in two of them the atropine treatment was maintained for more than 30 min. Since at the end of such prolonged applications of atropine, the responses of the L-horizontal cells of the same preparations were almost completely blocked (as it is the case in Fig. 3*e*), a participation of L-horizontal cells in the generation of the depolarising responses of hyperpolarising bipolar cells to the stimulation of the periphery of their receptor field can be excluded, except probably for some kind of tonic inhibition which would account for the increase of the surround responses under atropine.

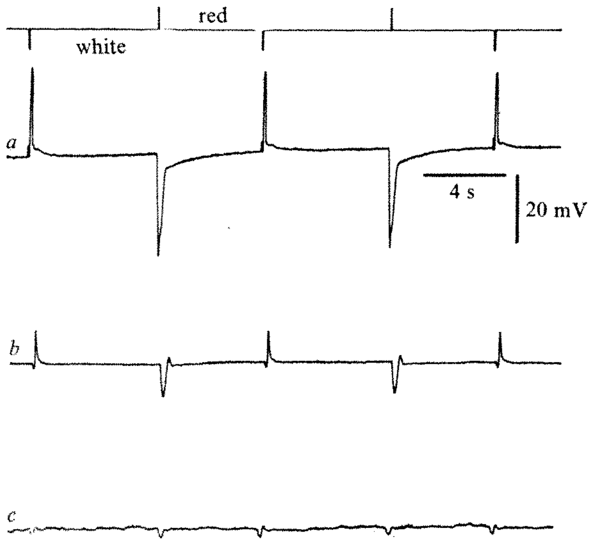

Fig. 2 Atropine effect on the responses of a green–red coded C-type horizontal cells. The top tracing marks the timing of the light stimuli, the red stimuli downwards, the white ones upwards. In (*a*) (control), the C-horizontal cell responded with depolarisations to stimulations with large spots of red light (650 nm, delivering 2.5×10^{14} photons cm^{-2} s^{-1}) and with hyperpolarisations when similar size spots of white light (relative intensity −1) were used. *b*, After applying atropine for 9 min, the C-horizontal all became hyperpolarised and both types of response seemed diminished in amplitude, but note that the hyperpolarising responses to red stimuli became preceded by a small short hyperpolarisation. *c*, After 15 min of atropine application, the responses were markedly reduced in amplitude and the red stimuli evoked only small hyperpolarising responses.

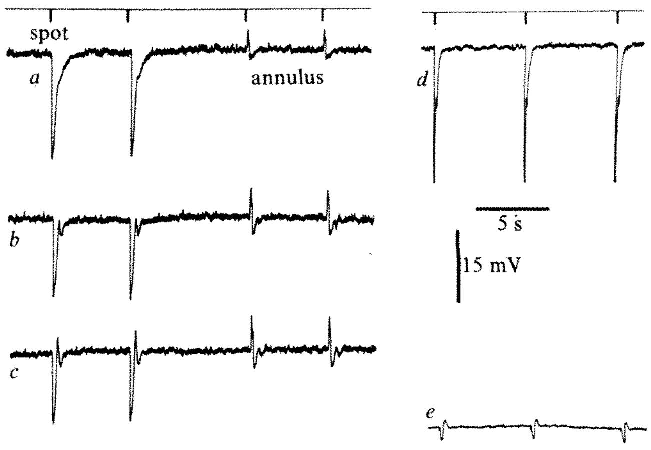

Fig. 3 At left (*a, b, c*), recordings from a hyperpolarising bipolar cell and at right (*d, e*) recordings from two different horizontal cells. The top traces on both sides mark the timing of the light stimulations. At left the two first stimuli in each row were centred light spots (diameter 380 μm, relative intensity −3) and the two following stimuli were white light annuli (internal diameter 500 μm, external diameter 3,600 μm; relative intensity −5). *a*, Control recordings of the bipolar cell response to the spot and annulus. *b*, After 10 min of atropine application, the central responses were slightly diminished and showed off-hyperpolarisations, whereas the responses to the periphery were increased in amplitude. *c*, After 20 min of atropinisation, the centre responses were not changed, except for the increasing complexity of the off responses, while the amplitude of the responses to the annulus had further increased. *d*, Recording from an L-horizontal cell impaled just before penetrating the bipolar cell at left, showing a hyperpolarising response to white light large spots (diameter 3,600 μm, relative intensity −3). The recording in (*e*) is from another L-horizontal cell penetrated at the end of the experiment, just after removing the pipette from the bipolar cell at left, while the preparation was still bathed in atropine. Notice the block of L-horizontal cell responses after more than 25 min atropine application.

It seems difficult at present to suggest what cellular elements of the retina are responsible for the antagonistic surround responses in the hyperpolarising bipolars of turtle retina. The two main possibilities, if this interaction takes place in the outer plexiform layer, are that either the periphery cones (through the long processes described by Lasansky[12] in *Pseudemys retina*) or other bipolar cells are responsible for generation of the surround responses of hyperpolarising bipolar cells.

We thank Mr Bernard Lacaisse for technical assistance and Mr G. Cappagli for the construction of an amplifier. Membrane control of cardiac contractility

ALL myocardial cells contract in every cardiac cycle and the contractility of the heart cannot be modulated as in skeletal muscle by varying the number of active cells, so each cardiac cell must be capable of a broad range of contractile states. Such versatility could result from changes in the action potential, in the amount of Ca^{2+} released for activation of the contraction, or in the contractile proteins themselves. Phosphorylation of the inhibitory subunit of troponin seems to occur in parallel with the increase in contractility of isolated hearts perfused with catecholamines[1,2], and studies using isolated proteins indicate that the phosphorylation may be associated with a change in ATPase activity[3,4], but a direct demonstration that the functional properties of contractile proteins themselves can be altered in a manner compatible with a physiologically important regulatory mechanism has not yet been produced. We report here studies of cardiac cells with membranes that have been made hyperpermeable, in which the response of the contractile system to Ca ions, the presumed trigger for activation of contraction, may be altered markedly with respect to both the concentration of calcium required for activation and the maximum generated force by the microenvironment of the contractile proteins and by reactions involving the cell's membranes. Cyclic nucleotides may be involved in some of these regulatory reactions.

For these experiments a bundle of cardiac cells from a rat right ventricle which had been 'functionally skinned' by chelating membrane calcium with EGTA was used[5]. The sarcolemma of these cells, though highly permeable to small molecules and ions, still retains large molecules such as creatine phosphokinase and pyruvate kinase which can easily be lost when the sarcolemma is removed. Proteins like adenylate cyclase and protein kinase, which may be involved in the regulation of the contractile system and which are relatively tightly associated with structural elements of the cell[6], should therefore be present in the skinned fibre and presumably responsive to changes in concentration of small inhibitory or stimulatory cofactors such as Ca^{2+}, Mg^{2+} and ATP in the bathing medium.

The force produced at any concentration of Ca^{2+} from 10^{-9} M, a level considerably below the normal threshold for activation, to 10^{-5} M, the optimal concentration for activation, can be increased by lowering the concentration of MgATP, and the maximum Ca-activated force in 0.02 mM MgATP is about twice that produced in 5 mM ATP, the approximate intracellular concentration. In addition to an increase in force production, which may be due to either more cross bridges bound to actin at a time or more force from each cross bridge, the threshold concentration of Ca required for activation is reduced, suggesting that the affinity of troponin for Ca has been enhanced. These observations are very similar to those made by Bremel *et al.*[7], on isolated myofibrils from skeletal muscles, but comparable experiments with a mechanically skinned cardiac cell, in which the sarcolemma has been removed, have not been done at the very low concentrations of MgATP (ref. 8).

Exposure of the EGTA-skinned fibres for several minutes to 5–20 μM Ca in the presence of a very low concentration of ATP produces a marked change in the contractile properties of the fibres (Fig. 1). Force, which is normally well maintained in 5 mM ATP, falls, and this decline continues for several minutes after the ATP concentration has been returned to 5 mM, indicating that the combination of low ATP and high Ca acts through an intermediate reaction and not directly on the contractile proteins. After several minutes in 5 mM ATP the fibres stabilise, but their response to activating concentrations of Ca in 5 mM ATP is now much weaker. The extent of the inhibition, which can be almost total, depends primarily on the duration of the soak in the solution with low ATP and high Ca. The requirements for the inhibition of force generation are 1 μM Ca or more and 20 μM ATP or less, but some ATP must be present. If the membranes of the skinned fibres have been disrupted with the non-ionic detergent Brij for 45 min, a reduction of ATP to only 1–2 mM is necessary, but the Ca requirements remain unaltered. Apparently two reactions, one ATP

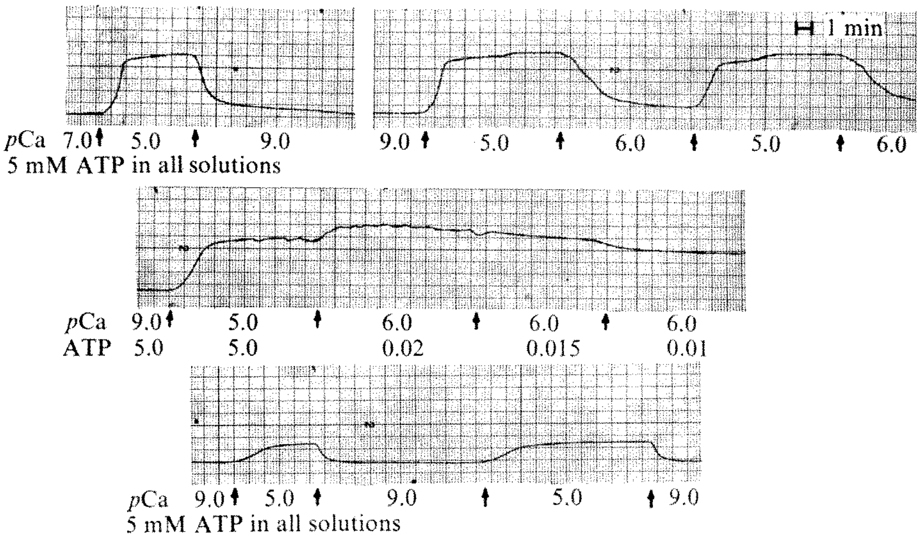

Fig. 1 Force record produced by a rat ventricular trabecula which had been functionally skinned by an overnight soak at 4 °C in a solution containing 10 mM EGTA, 4 mm MgAc$_2$, 5 mM ATP and 120 mM K propionate. The numbers under the records indicate the *p*Ca (–log[Ca^{2+}]) and the concentration of ATP in the bathing solution. The force developed in 5 mM ATP during maximal activation is very reproducible in each of the first four exposures, but when the ATP concentration is lowered to 0.01–0.02 mM the force declines. After return to 5 mM ATP the force in optimal *p*Ca is again stable, but it has been markedly reduced. The shape of the tension–Ca relation is the same after the exposure to low ATP as it was before; a uniform relative decrease in force at each concentration of Ca has occurred. In all solutions the concentration of free Mg^{2+} ions was held constant at 2 mM after taking into consideration its interactions with ATP, EGTA and creatine phosphate. The MgATP concentration was controlled by varying ATP concentration; in view of the large excess of Mg ions it was assumed that all ATP was in the form of MgATP. Ca^{2+} was buffered with 3mM EGTA and ATP with 15 mM creatine phosphate. Creatine phosphokinase, although present in high activity in the tissue, was also added with the creatine phosphate. In most experiments ionic strength was maintained by varying the concentration of KCl, but the inhibition of contractility produced by the combination of low ATP and high Ca was not particularly sensitive to ionic strength. The phenomenon occured in solutions with ionic strengths of approximately 0.7 to 1.5 times the usual value, which was approximately equivalent to 170 mM KCl. The *p*H was buffered at 7.0 with either 25 mM imidaxole or Tris at the equivalent ionic strength, and the results were independent of the specific buffer which was used. The standard test solutions with different *p*Ca that were used before and after the exposure to low ATP were identical in composition.

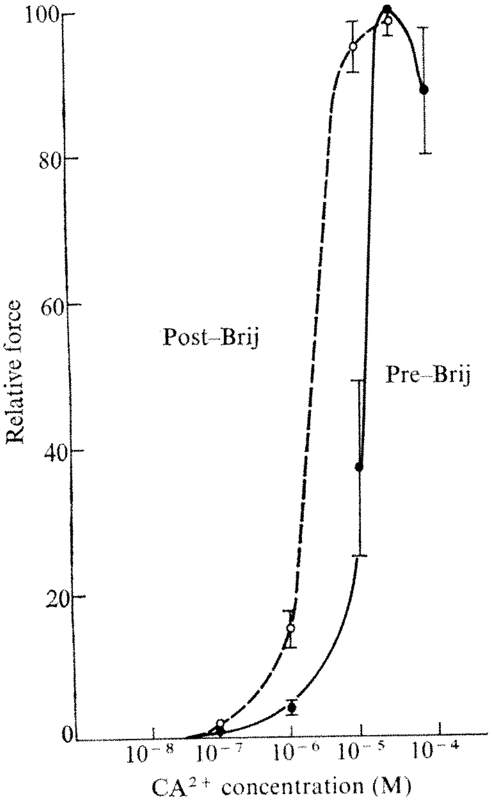

Fig. 2 The effect of the treatment of an EGTA-skinned rat ventricular bundle with Brij on the relation between force and Ca concentration. The solid curve indicates the values obtained in five preparations before Brij treatment and the interrupted curve, the values for the same muscles after 45 min in 0.5% Brij 58 followed by 60 min of washout in the standard bathing solution with no added Ca. The shift which is produced by Brij treatment has not been seen in skinned preparations where the surface membrane had been manually removed before the exposure to the detergent[9]. The Ca–tension relation found in the EGTA-skinned fibre after Brij treatment closely resembles what has been observed with the manually skinned cardiac muscle fibre[9].

dependent and requiring membranes and the other Ca dependent and not needing membranes, are involved in the change in contractility.

Exposure to Brij 58 or another detergent, Triton X-100, increases the sensitivity of the contractile system to Ca by a factor of almost 10 without altering the basic shape of the relation between Ca and force (Fig. 2). This is in contrast to the absence of any effect of Brij on the tension–Ca relation in cardiac cells from which the surface membrane had been completely removed manually[9]. A similar shift of the curve along the Ca concentration axis is produced by 5 mM theophylline or an experimental phosphodiesterase inhibitor (Squibb 20009). Apparently a nucleotide cyclase located in the membrane is involved in the regulation of the Ca sensitivity of the contractile proteins.

The effect of low ATP and high Ca on skinned fibres can be modified by the addition of sarcolemma vesicles[10] to the bathing medium. Their presence in the low ATP–high Ca solution prevents the decline in contractility, and their addition to a normal Ca-activating solution restores the original contractility to an inhibited muscle bundle for as long as the membrane vesicles remain in the bathing solution (Fig. 3). Addition of the membrane fraction to the solution bathing a non-inhibited skinned fibre causes little or no change in its contractile response to Ca. Since the preparation retains a functional diffusion barrier at its surface, the membrane vesicles are unlikely to be entering the cells and are more likely to be producing a substance which diffuses into the cytoplasm.

The capacity of the contractile system for generating force may, therefore, be controlled, at least in part, by the net result of two reactions. One reaction involving the cell membranes maintains a high capability for force generation, and the other, probably located in the myofibril, depresses the ability of the system to produce tension. The membrane reaction does not seem to involve the contractile system directly, but rather to suppress either the synthesis of an inhibitory molecule or the interaction of an inhibitory molecule with the contractile proteins. In view of the importance of the sarcolemma and the apparent inhibition by ATP concentrations below 20 μM, the first reaction may be associated with the production of cyclic AMP and the requirement of the second reaction for ATP

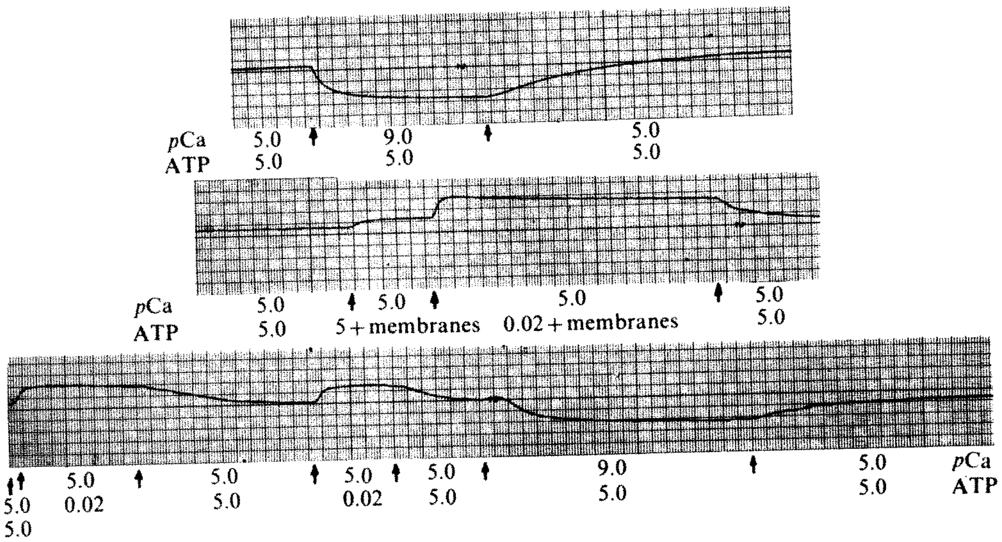

Fig. 3 The presence of isolated sarcolemmal vesicles in the bathing medium protects the EGTA-skinned rat ventricular cells from the negative inotropic effect of an exposure to the combination of low ATP and high Ca. Numbers under the force record indicate *p*Ca and mM ATP. Force in optimal Ca and 5 mM ATP is reproducible. The exposure of the tissue to *p*Ca 5.0 and 20 μM ATP does not inhibit the subsequent ability of the tissue to generate force on *p*Ca of 5.0 when sarcolemma vesicles (prepared according to Lefkowitz and Haber[10]) are present in the bathing medium. Since the membranes which were added did not show any Ca-activated ATPase, major contamination with sarcoplasmic reticulum is unlikely. ATP concentration was buffered with 15 mM creatine phosphate, which was at least 5 mM in excess of what was necessary to prevent any detectable sign of ATP limitation. Direct measurements of the bathing solution showed that the presence of the membranes caused a decline in creatine phosphate of only 1.5 mM every 30 min. The presence of 15 mM creatine phosphate at the beginning of a force measurement satisfactorily maintained the ATP concentration. The membrane fraction in the bathing solution represented an approximately 100-fold dilution of the concentration of membranes in the original ventricle, and consequently, its presence would contribute very little to the ionic strength or osmolarity of the bathing solution. The temporary protection from the presence of the membranes disappears with their removal as shown in the record, but in the absence of an exposure to low ATP without membranes, tension is well maintained for several hours after the exposure to low ATP with membranes. The small rise in force when membranes were added to the bathing solution was sometimes seen. It was completely reversible and was probably due to a temporary reversal of a small amount of existing inhibition of contractility.

suggests a Ca-regulated phosphorylation[11]. Experimentally, however, the addition of cyclic AMP or cyclic GMP alone has failed to reproduce the effect of the low ATP–high Ca solution, the membrane fraction or Brij treatment. If our inferences about their involvement are valid, the cyclic nucleotides can be active only in very specific conditions, and alteration of contractile proteins is controlled by a pattern of molecules and not by a single molecular species. The sensitivity of the potentially responsive fraction of the contractile proteins to Ca is also regulated by the sarcolemma, possibly through a cyclic nucleotide controlled phosphorylation of the contractile proteins[4].

The sensitivity of the contractile system to the concentration of ATP may represent a protective mechanism available to the cell for conserving energy for life sustaining reactions when the supply of oxygen or substrate is deficient. It would constitute a mechanism whereby the work of the tissue could be adjusted to its energy supply.

Postsynaptic effects of a multiaction giant interneurone on identified snail neurones

A FEW examples of identifiable neurones which have widespread monosynaptic and multi-action effects on large numbers of postsynaptic cells have been found in gastropod molluscs[1–3]. Such neurones are of considerable interest to neurophysiologists attempting to understand how the electrical activity of large networks of nerve cells can be integrated. We report here that the right pedal giant neurone (RPGN) of the pond snail, *Lymnaea stagnalis* (L.), is an interneurone with monosynaptic connections with many previously identified giant cells[4] and cell clusters[5] situated on the visceral and right parietal ganglia of *Lymnaea.* The RPGN mediates excitation on some cells, inhibition on others and biphasic effects (excitation followed by inhibition) on yet other cells.

Isolated brains from 1–9-g specimens of *L. stagnalis* were prepared for electrophysiological recording as previously described[5], except that the commissure between the cerebral ganglia was cut and the ganglia spread apart. This procedure facilitated simultaneous electrophysiological recording from the RPGN in the right pedal ganglion and from its follower cells on the dorsal surfaces of the visceral and right parietal ganglia. Intracellular recordings were obtained from neuronal somata using conventional recording methods and 10–20-MΩ K_2SO_4 filled microelectrodes. Preparation of electrodes was greatly facilitated by use of triangular cross-section Pyrex electrode glass which allowed rapid, reliable filling of microelectrodes with electrolyte without previous addition of glass fibres.

The RPGN lies on the postero-ventral surface of the right pedal ganglion, medial to the statocyst and has a major soma diameter within the range 120–240 µm in different snails. The positions of the cell bodies of neurones innervated by the RPGN are shown in Fig. 1. RPGN action potentials evoked by intracellular injection of depolarising current pulses via the recording electrode result in excitatory postsynaptic potentials (e.p.s.p.s) in A group (Fig. 2*a*), the H cells (Fig. 2*e*) and K cells (Fig. 2*b, c, d*), inhibitory postsynaptic potentials (i.p.s.p.s) in the J cells (Fig. 2*b, c, d*) and VD2, VD3 (not shown) and a biphasic response (excitation followed by prolonged inhibition) in G group (Fig. 2*i, j*).

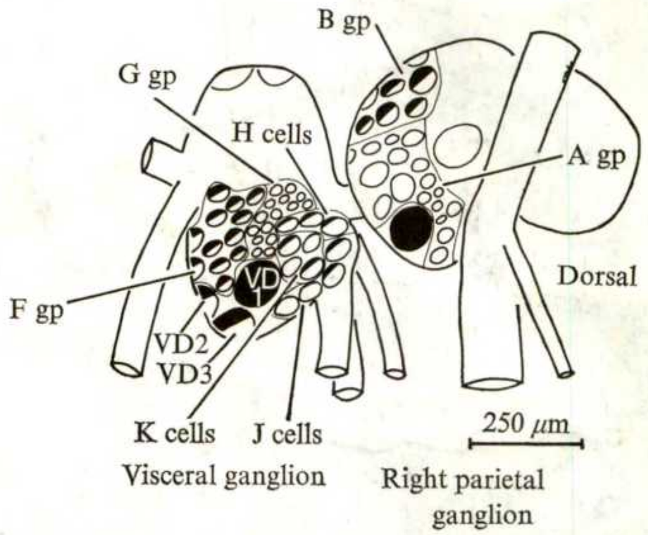

Fig. 1 Diagram of the visceral and right parietal ganglia of *Lymnaea* from the dorsal aspect. The cell body positions of several giant cells and cell clusters are indicated. Most of the neurone somata are orange in colour (unshaded), but some are pale (part shaded) and others white (filled), probably due to the light-scattering properties of small granules present in the cytoplasm. The H, J and K cells are difficult to separate from one another by appearance alone and do not necessarily lie in discrete clusters, but G group is a distinct cluster of small orange cells of 30–50 µm soma diameter. The cell bodies of A group are of variable size, but have similar properties to one another. The somata of the giant cells VD2 and VD3 (visceral dorsal cells 2 and 3) usually lie on the dorsal surface, but may sometimes be found ventrally along with the soma of VD1. The cell bodies of F group and B group spread on to the ventral surfaces of the visceral and right parietal ganglion respectively. Neither they nor VD1 receive inputs from the RPGN, but they share some common inputs with it and with the cells it innervates.

Several lines of evidence suggest that these connections are monosynaptic:

(1) One postsynaptic potential per spike could be evoked up to the maximum frequency of firing of the RPGN (about 10 Hz) (Fig. 2*a, b*).

(2) The delay between the onset of the spike in the RPGN and the start of the postsynaptic response was constant for a particular neurone (20–25 ms for e.p.s.p.s, Fig. 2*a* and *b*) even after treatment in a solution containing five times (20 mM) the usual Ca^{2+} concentration (Fig. 2*f, g, h*). The delay was more difficult to determine for i.p.s.p.s because of their slow rise time.

(3) Bathing the preparation for up to 2 h in this high Ca^{2+} saline failed to block excitatory (Fig. 2*e, f, h*) inhibitory (Fig. 2*g*) or biphasic effects. High Ca^{2+} saline would be expected to raise the threshold of any interneurone lying between the RPGN and a follower cell, thus causing synaptic block[7].

(4) Iontophoretic injection of tetraethylammonium (TEA) into the RPGN via a recording electrode containing 1 M TEA bromide resulted in a prolonged action potential and a corresponding increase in the duration of the postsynaptic response (shown for a G group biphasic response in Fig. 2*i, j*). We presume that injected TEA has the effect of blocking the delayed increase in K^+ conductance during the action potential[8], thereby prolonging the release of transmitter, and increasing the duration of the postsynaptic response in the case of a monosynaptic connection. On the basis of this evidence it seems reasonable to summarise the connections of the RPGN with its follower cells as shown in Fig. 2*k*. Further inputs common to the RPGN and its follower cells are summarised elsewhere[6].

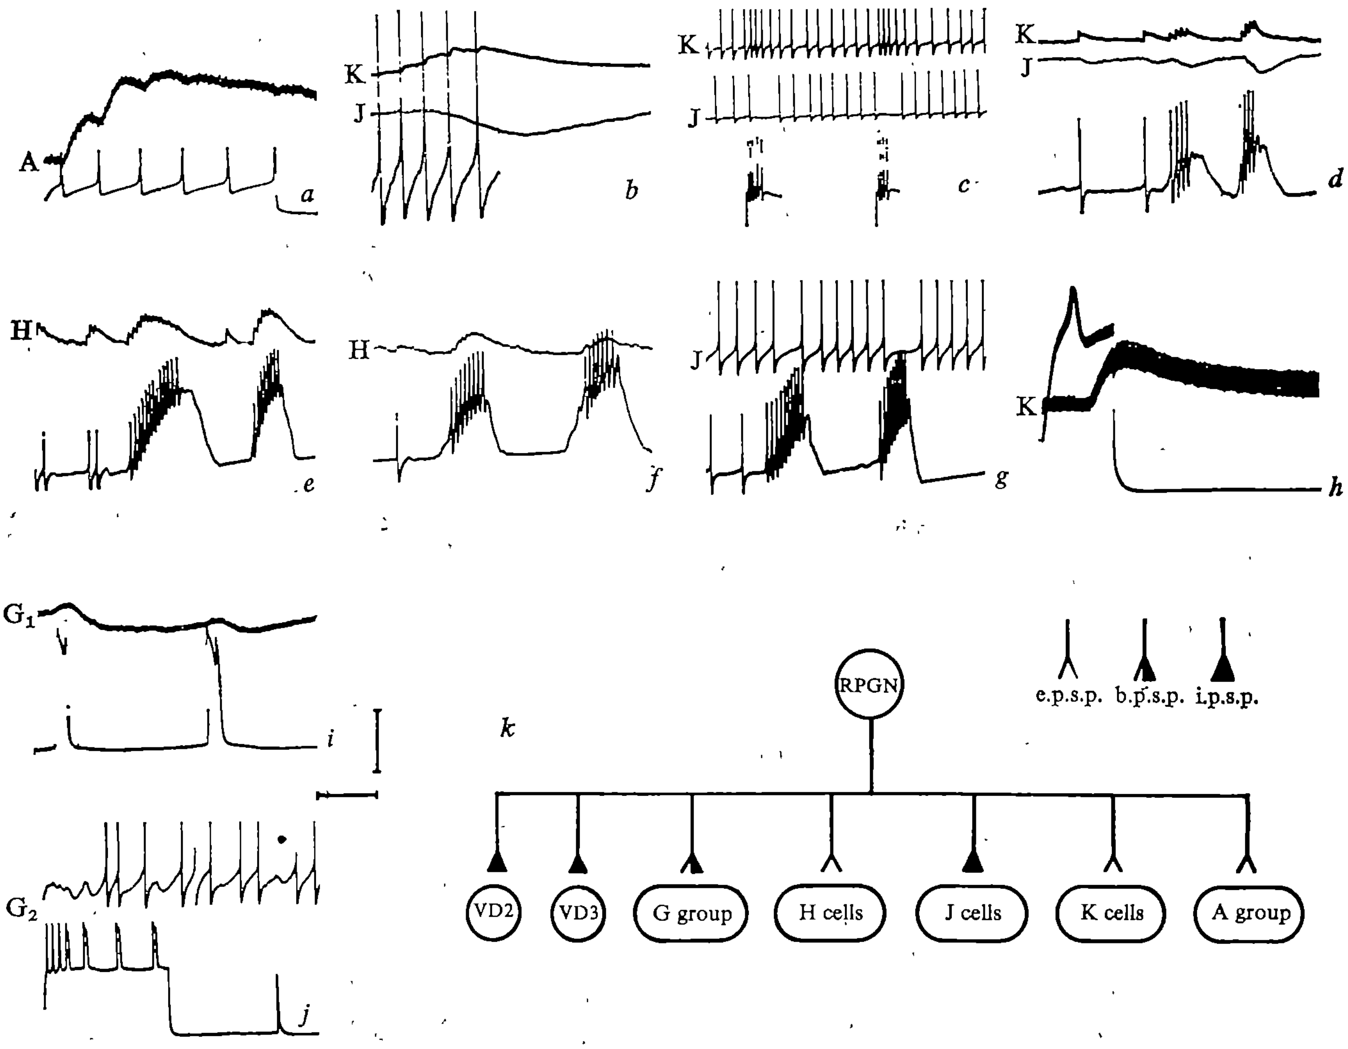

Fig. 2 Monosynaptic connections between the RPGN and its follower cells. The RPGN is on the lower trace in all cases. Other traces are from follower cells of the RPGN labelled with capital letters in accordance with Figs 1 and 2*k*. Excitatory inputs are received by the cells of A group (*a*), the K cells (*b*, *c*, *d*) and H cells (*e*), whilst i.p.s.ps are received by the J cells (*b*, *c*, *d*) and biphasic p.s.ps (b.p.s.ps) are found in the cells of G group (*i*, *j*). To demonstrate the 1:1 relationship and constant latency between spike and p.s.p. it is necessary to hyperpolarise the follower cells (*a*, *b*, *d*, *e*) by 5–15 mV since at the follower cells' normal firing level these effects cannot be clearly seen (*c*). The RPGN follower cell connections are not blocked by high Ca^{2+} saline (*f*, *g*, *h*). *f*, The same H cell as in (*e*) shown after soaking the preparation for 17 min in high Ca^{2+} saline. The e.p.s.ps are diminished in amplitude since increased Ca^{2+} levels cause a depolarisation of the G cells rather than a hyperpolarisation. cell RPGN spikes are increased in amplitude since they are partially Ca^{2+} dependent. *g*, High Ca^{2+} saline fails to block inhibition of a J cell by the RPGN; *h*, 20 repetitions of a spike in the RPGN, evoked by a 100-ms pulse at 0.5 Hz, cause a stable e.p.s.p. in a K cell after immersion in high Ca^{2+} saline for 15 min. The effects of TEA on the RPGN spike and on the b.p.s.ps recorded in two different G cells from the same preparation are shown in *i* and *j*. The b.p.s.ps are considerably enhanced and have durations in excess of 1.2 s compared with control durations of 0.5–0.7 s. In normal conditions the initial excitatory phase is usually very small or even suppressed. *i*, G_1, 310 min after the start of iontophoretic injection of the RPGN. *j*, G_2, 330 min after the start of TEA injection (0.5-s pulses at 1 Hz). *k*, Summary diagram of the monosynaptic connections of the RPGN. Time calibrations: *a*, 0.4 s; *b*, 0.8 s; *c*, *d*, 8 s; *e*, *f*, 2 s; *g*, 4 s; *h*, 0.1 s; *i*, 1 s; *j*, 4 s. Voltage calibrations: *a*, upper 4 mV, lower 100 mV; *b*, all traces 20 mV; *c*, all traces 80 mV; *d*, upper 20 mV, middle and lower 40 mV; *e*, *f*, upper 20 mV, lower 100 mV; *g*, upper 40 mV, lower 100 mV; *h*, upper 10 mV, lower 80 mV; *i*, upper 10 mV, lower 40 mV; *j*, upper 20 mV, lower 100 mV.

Sakharov[4] has demonstrated that the RPGN of *Lymnaea* is catecholaminergic and Kiss[10] indicated that several cells in the visceral and right parietal ganglia respond to iontophoretically applied dopamine with either depolarising or hyperpolarising shifts in membrane potential. Although the precise identity of these cells is as yet unclear they occur in similar areas of the ganglia to those described here and presumably correspond to some of the cells we describe. Thus the RPGN is most probably dopaminergic and therefore homologous with another multi-action neurone making widespread monosynaptic connections, the giant dopamine-containing cell (GDC) of *Planorbis corneus*[3]. The brain of *Planorbis* (a sinistral pulmonate) is a mirror image of that of *Lymnaea*. Thus the GDC lies on the left pedal ganglion and its follower cells lie on the visceral and left parietal ganglia. Unfortunately, none of the follower cells in *Planorbis* has been identified and it is not yet possible to say whether they correspond with the identified neurones we have described in *Lymnaea*.

Spontaneous release of transmitter from 'repressed' nerve terminals in axolotl muscle

DENERVATION of the limb of a lower vertebrate is followed by an ordered reinnervation, so that the normal pattern of muscle use is restored[1]. Higher vertebrates, however, seem to be much less selective in their reinnervation[2]. There is no absolute restriction on inappropriate reinnervation in lower vertebrates[3]; the return of normal function is due, at least in part, to multiple reinnervation of muscle fibres by different nerves, followed by a repression of function of less appropriate contacts[4]. Yip and Dennis[5] have shown that the repression of function in inappropriate nerve–muscle junctions in the newt, *Notopthalmus viridescens*, involves a reduction in the number of quanta of synaptic transmitter released by each nerve impulse. If the initiating event in this process is reduction or loss of the ability of inappropriate nerve terminals to release transmitter[6,7], there should be evidence of the continued presence of these terminals even after transmission from the inappropriate nerve has been repressed. In this paper we present such evidence as a result of our studies in the axolotl.

Sectioning the anterior nerve to the supracorocoideus muscle of axolotls (*Ambystoma mexicanum*) induces the posterior nerve to sprout and innervate muscle fibres normally activated by the anterior nerve. This inappropriate innervation is subsequently repressed when the anterior nerve regenerates and reinnervates its normal territory[8] (Fig. 1). In our experiments, the anterior nerve was sectioned initially and then again, 20–100 d after the first cut, so as to cause the newly restored anterior nerve terminals to degenerate once again. Nerve–muscle transmission from anterior nerve terminals failed about 24–30 h (December–January) or 48–54 h (May–June) after this second section (similar seasonal differences in the time of survival of axotomised nerve terminals occur in frogs[9,10]). Shortly after this failure, intracellular recording revealed low frequency miniature endplate potentials (m.e.p.ps) in regions of the muscle where repressed nerve terminals were anticipated to exist (Fig. 1*d*), and not elsewhere (Fig. 2). These m.e.p.ps were not seen if both anterior and posterior nerves were sectioned. (Thirty-six cells were examined in two muscles. Muscles from the contralateral limbs were given the same initial operation but the posterior nerves were left intact in the second operation. Eight of 24 cells in the contralateral muscles had the low frequency m.e.p.ps.) Stimulation of the intact posterior nerve evoked no responses in muscle fibres exhibiting these low frequency m.e.p.ps.

This population of m.e.p.ps had properties distinguishing them from those recorded at degenerating terminals, those seen at developing nerve–muscle junctions at the stage before nerve–muscle transmission has developed[10], and also from those caused by ACh release from denervated Schwann cells a few days after nerve–muscle transmission has failed[11]. Degenerating anterior nerve terminals continued to release m.e.p.ps for 1–4 h after nerve-evoked transmitter release had failed and they occurred at multiple sites along the length of each muscle fibre, whereas the low frequency m.e.p.ps which remained after the degenerating terminals had ceased to release transmitter usually occurred at a single site near the distal end of a muscle fibre; their further characteristics are listed in Table 1.

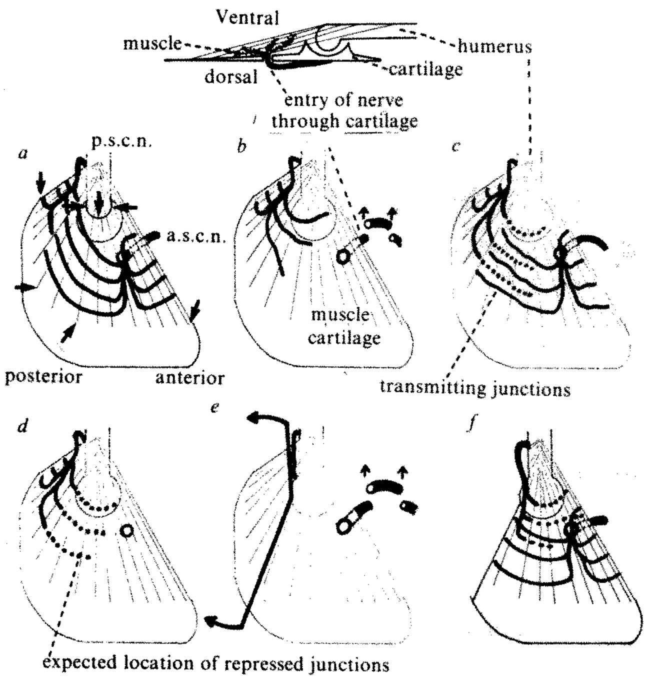

Fig. 1 Experimental scheme to locate repressed nerve–muscle junctions. Top, transverse section view through supracorocoideus muscle and cartilage; *a–f*, ventral views. The supracorocoideus muscle in the shoulder girdle of the axolotl has two separate zones of innervation (*a*). Cutting the anterior nerve (a.s.c.n.) provokes the posterior nerve (p.s.c.m.) to extend its transmission zone into more anterior regions of the muscle (*b*). Later, (*c*), the anterior nerve regenerates and resumes control of the large anterior zone of the muscle, and transmission to this zone by the posterior nerve (dotted lines) is repressed[8]. We cut the anterior nerve a second time, and shortly after its degenerating terminals had ceased to release transmitter, explored the muscle for evidence of repressed nerve–muscle junctions (*d*). In a second series of experiments (*e*, *f*) the whole posterior zone of the muscle was removed at the time of anterior nerve section so that any contacts between the posterior nerve and the muscle seen at a later time could be judged inappropriate. Supracorocoideus muscle fibres are multiply innervated by axons from one or the other nerve, and respond to nerve stimulation with action potentials. For microelectrode recording much of the cartilage was removed and the muscle approached from the dorsal (cartilage) side. The reference points marked by arrows (*a*) were mapped for each muscle using a 20× water immersion objective and the microscope stage micrometer so that relative positions of recording sites in muscles of different sizes could be compared by transferring these coordinates to a common schematic. The axolotls used in this work were all from the same mating and hatched in September 1975.

Lanthanum ions increase m.e.p.p. frequency at normal and developing nerve–muscle junctions[10,12]. In control experiments, using normal muscles, 0.5 mM $LaCl_3$ caused a 10–100-fold increase in m.e.p.p. frequency within 30 s of its addition to the perfusion system. Most applications to experimental preparations were of 2 mM $LaCl_3$, and in about half 10 mM HEPES buffer (*p*H 7.2) was added to avoid problems of excess acidity or precipitation of La^{3+}. Twenty-three muscle fibres with low frequency m.e.p.ps seen shortly after failure of anterior nerve transmission were examined for 2 min or more during perfusion with La^{3+} Ringer with a resolution of recording of 0.2 mV or better. In 19 fibres there was no change in m.e.p.p. frequency (less than twofold increase or decrease) during application of the La^{3+}. Two fibres responded with a large increase in m.e.p.p. frequency. In two more there was a slowly developing increase after an initial latent period; for example, control frequency 5 per 30 s; La^{3+} induced, 7, 6, 10, 30, and 51 per 30 s respectively.

Depolarisation of normal or developing nerve–muscle junctions by adding KCl to the bathing medium causes a prompt and maintained increase in m.e.p.p. frequency[10]. In control experiments with normal muscles, KCl concentrations of 15 or 17.5 mM caused an increase in m.e.p.p. frequency at least tenfold within seconds of its addition to the bath, whereas muscle fibres were not so depolarised that m.e.p.ps were

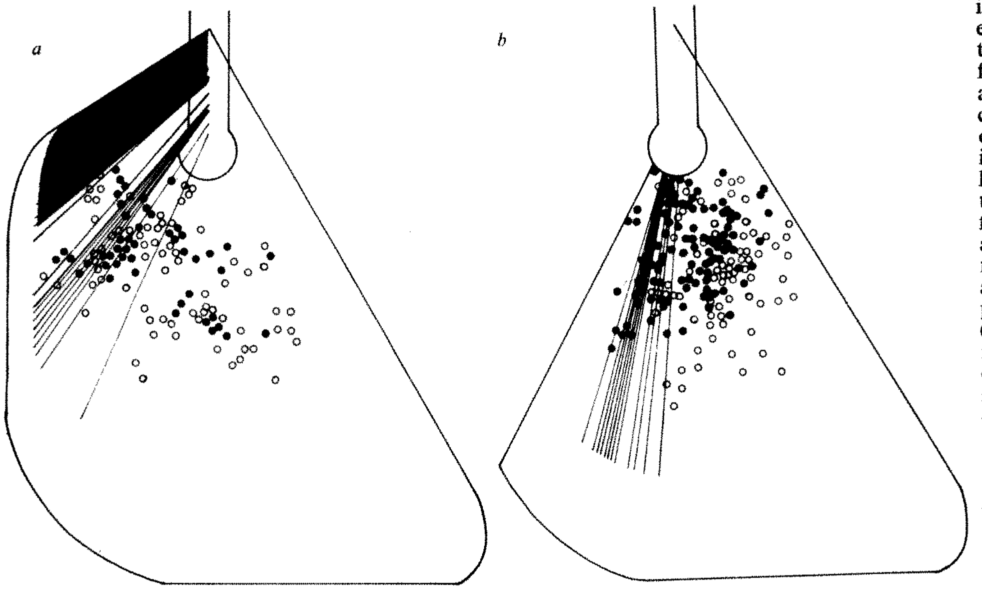

Fig. 2*a* Posterior nerve innervation zone and location of low frequency m.e.p.ps in supracorocoideus muscles following expansion and retraction of the posterior nerve innervation zone. Records from both left and right muscles from animals ranging in length from 5 to 13 cm have been placed on a common diagram using the reference points illustrated in Fig. 1*a*. ●, Fibres with low frequency m.e.p.ps and no response to posterior nerve stimulation; ○, fibres with no m.e.p.ps over a period of at least 2 min stable recording with resolution 0.2 mV or better. Shaded area, fibres contracting in response to posterior nerve stimulation in normal (control) muscles; /, borders of posterior nerve-induced contraction in individual experimental muscles. The diagram summarises results from 16 muscles examined 20–52 d after the initial section of the anterior nerve (in seven muscles the nerve was resectioned 3 weeks after the initial operation, and the muscles examined 2–3 weeks later). The anterior nerve was again sectioned 24–96 h before recording from all of the muscles. Degenerating anterior nerve terminals ceased to release transmitter 24–30 h after nerve section in these animals. Low frequency m.e.p.ps with the special properties described in the text could be identified only anterior to the border of posterior nerve–muscle transmission. This border had retracted to within its normal limits in less than half the muscles examined in this series. These experiments were carried out during January and February 1976. *b*, Nerve–muscle transmission and low frequency m.e.p.ps in preparations with the posterior portion of muscle removed at the time of anterior nerve section. Symbols as in *a*. This is a summary of results from 16 preparations examined 3 months after the initial operation, and 29–120 h after second section of the anterior nerve. These animals ranged in size from 14 to 19 cm, so anterior nerve regeneration generally took longer than in the muscles illustrated in *a*. The experiments were carried out during May and June 1976. In these experiments all muscle fibres became reinnervated by the anterior nerve, but 12 of 16 muscles retained a zone of posterior nerve innervation so that dually innervated muscle fibres occured near the posterior border of many muscles.

difficult to see. We examined 17 junctions with low frequency m.e.p.ps seen shortly after failure of anterior nerve transmission. In 14 of these there was no change in m.e.p.p. frequency (less than twofold increase or decrease) during at least 1 min of muscle depolarisation caused by perfusion with high K^+ Ringer (the muscle cell depolarisation served to monitor the effective presence of the K^+). In two fibres there was a prompt and large increase in m.e.p.p. frequency and in one fibre it began to increase 2 min after addition of the K^+ (control frequency 4 min^{-1}; K^+, 4 min^{-1}, 7 min^{-1}, 25 min^{-1}).

Slowly developing increases in m.e.p.p. frequency in response to La^{3+} or K^+ perfusion were more commonly seen when more time elapsed after anterior nerve section. For example, in muscles examined 5 d after nerve section five fibres treated with La^{3+} showed no change in frequency during the first 2 min of perfusion, but increased an average of six times during the third minute. Similarly, three fibres treated with high K^+ showed a sixfold increase in m.e.p.p. frequency during the third minute. Also, at this time, a few fibres were found where posterior nerve stimulation intermittently evoked small e.p.ps. Genat and Mark[8] found that transmission at repressed junctions in axolotl supracorocoideus muscle began to return 7 d after section of the regenerated anterior nerve. The slight restoration of sensitivity of m.e.p.p. frequency to La^{3+} or K^+ seen 5 d after anterior nerve section may mark a return towards normal function.

Increased tonicity raises m.e.p.p. frequency at normal and developing nerve–muscle junctions[13,14]. Twenty-one fibres with low frequency m.e.p.ps were tested by application of Ringer solution made hypertonic by addition of 55 mM Na_2SO_4. In 20 of these fibres m.e.p.p. frequency increased at least fivefold. Seven fibres were tested with La^{3+} and K^+ in addition; mean m.e.p.p. frequencies were: control, 10 min^{-1}; K^+, 14 min^{-1}; La^{3+}, 8 min^{-1}; hypertonic, 145 min^{-1}.

Botulinum toxin blocks nerve-evoked transmitter release and greatly reduces spontaneous m.e.p.p. frequency without affecting synaptic structure or propagation of the presynaptic action potential[15]. We treated normal axolotl muscles with large doses of type D botulinum toxin and found that the resulting low frequency m.e.p.ps had properties similar to those seen following repression of inappropriate nerve terminals. Seven botulinised fibres examined in normal Ringer had a mean m.e.p.p. frequency (±s.e. of the mean) of 0.10 ± 0.04 min^{-1}; in hypertonic Ringer 9.9 ± 5.8 min^{-1}; and in KCl Ringer 0.14 ± 0.04 min^{-1}.

The low frequency m.e.p.ps seen in the experimental muscles resembled those released from Schwann cells at denervated endplates in that their frequency was unaffected by treatment

Table 1 Properties of miniature endplate potentials at normal, developing, degenerating, denervated and repressed nerve–muscle junctions

Agent	Junction				
	Normal	Developing	Degenerating	Denervated (Schwann cells)	Repressed
Nerve stimulation	e.p.p. or a.p.	No effect	Variable	No effect	No effect
Nerve section	Abolished	Abolished	—	No effect	Abolished
Frequency (min^{-1})	10–60	0.2–60	0.2 to very high, in bursts	0.2–10	0.2–10
La^{3+}	Increased frequency	Increased frequency	Increased frequency	No effect	No effect
K^+	Increased frequency	Increased frequency	Increased frequency	No effect	No effect
Hypertonic solutions	Increased frequency	Increased frequency	Not tested	No effect	Increased frequency

with La^{3+} ions or by raised K^+ in the bathing medium[10]. Unlike Schwann-released m.e.p.ps, they were very sensitive to increased tonicity of the bathing medium, and no 'silent period'[10,11] elapsed before they could be seen (we saw no Schwann m.e.p.ps in axolotl muscles kept fully denervated for up to 42 d, in spite of recording close to old endplates).

The unique properties of these m.e.p.ps (Table 1), together with their territorial distribution in experimental muscles (Fig. 2), and their dependence on the integrity of the posterior nerve, distinguish them from other classes of m.e.p.ps, and we suggest that they are released from nerve terminals whose normal function has been repressed (and possibly also from developing inappropriate nerve terminals whose maturation has been arrested).

On the basis of our observations we propose that repression of transmission at inappropriate junctions in axolotl muscle is due to a change in or loss of the Ca^{2+}-dependent mechanism[16,17] involved in transmitter release from nerve terminals. At normal and developing endplates La^{3+} ions seem to affect transmitter release by activating this Ca^{2+}-dependent process[12], and the effect of K^+ ions on transmitter release requires the presence of Ca^{2+} (ref. 14). On the other hand, the effect of hypertonic solutions is independent of the presence of Ca^{2+} (ref. 14). Also, the properties of the 'repressed' m.e.p.ps were mimicked by botulinising normal nerve terminals, and it has recently been shown that m.e.p.p. frequency in botulinised nerve–muscle preparations is returned to normal by treating them with a calcium ionophore in the presence of high external Ca^{2+} (ref. 18). We do not know how long functionally repressed junctions may remain physically present in a muscle.

We thank Professor Richard Mark for advice and provision of laboratory space and animals during the study, and the Australian National University for Visiting Fellowships to A. J. H. and L. Z. This work was supported by the New Zealand Medical Research Council.

Are transmitter release statistics meaningful?

A BASIC premise of synaptic physiology is that neurotransmitter is released from motor nerve terminals in multimolecular packets called quanta[1,2]. The rate of release of quanta is low at rest, but when an action potential invades the nerve terminal there is a large increase in the mean rate of release leading to the generation of an endplate potential. It has been found that the distribution of the number of quanta released by an action potential is accurately described by a binomial distribution[3–8]. The assumption which underlies the binomial process is that n independent units (quanta) each have the same probability of success (release), p, on a single trial (stimulation). The parameters n and p can be estimated from the mean and variance of the binomially distributed variable. Although it is not clear what the physical correlates of n and p might be, it has been suggested that n may refer to the number of releasable quanta[1], or to the number of release sites which can be activated on stimulation[6]. The changes in the apparent values of n and p which occur during synaptic processes such as facilitation[6,8] and depression[7], have been interpreted as providing evidence for particular mechanisms which may underly those processes.

Recent studies have shown that the probability of quantal release, either spontaneous or evoked, is increased after a spontaneous release[10,11]. This suggests that in normal conditions p and/or n may vary with time. The bursts of spontaneous release produced by the addition of brown widow spider venom occur at localised areas of the nerve terminal[12], suggesting that spatial variations in p or n may exist. Studies of the changes in the apparent values of n and p which occur during neuromuscular depression have been interpreted as indicating that the release probability may be different for different quanta[7]. These experimental findings have led us to investigate the implications of a distribution of quantal release probabilities. As a result of these studies we believe that the application of the binomial distribution to transmitter release may not be appropriate.

A simple example can easily demonstrate the effects of a distributed probability of release. Consider an experiment in which the mean quantal content, m, is equal to 16 and the variance, σ_m^2, is equal to 8. Since $m = np$ and $\sigma_m^2 = np(1-p)$ for a binomial process it is easy to show that $p = 0.5$ and $n = 32$. An identical mean output and variance could, however, be obtained from a population of 50 quanta, 10 with a probability of 0.8 and the rest with a probability of 0.2 Simple examples like this show that a distributed probability can cause large errors in the estimation of binomial parameters from the mean and variance of the quantal contents. Before this conclusion can be accepted however, it is necessary to demonstrate that the shape of the distribution of quantal contents cannot be distinguished from the binomial prediction by goodness-of-fit statistics. A computer simulation was necessary to generate and compare the actual and the predicted distributions. A number of different probability distributions were investigated, produced by defining a new variable $z = \log_e p/(1-p)$ and generating a normal distribution of z with mean z and variance σ_z^2. The z values were then converted back into p values. The main advantage of this approach is that a family of distributions of p can be generated which have no quanta at $p = 0$ or $p = 1$. A trial was then run by generating rectangularly distributed random numbers and comparing them in turn with the elements of the p distribution. If the value of p for a quantum was more than the random number then that quantum was counted as being released in that trial. A number of trials were run until a smooth distribution of quantal contents was obtained. Figure 1 illustrates the results of one simulation in which most of the 100 quanta had very low probabilities of release. One hundred trials were simulated. There is no significant difference between the simulated distribution of quantal contents and that predicted for a binomial process ($\chi^2 = 4.98$ with 5 d.f., $P > 0.25$). It is interesting to note that only 1% of the quanta have probabilities of release equal to, or greater than the estimated mean probability of release.

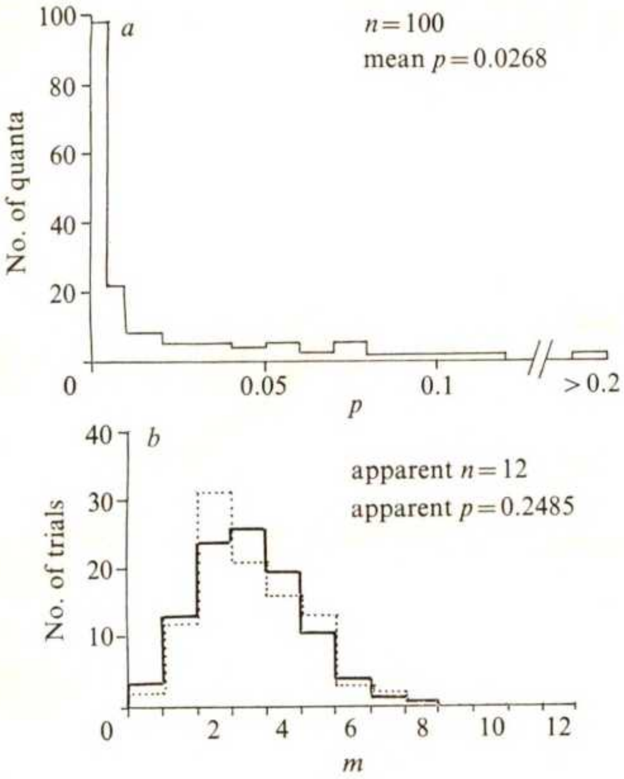

Fig. 1 The results of the simulation. *a*, Distribution of the probability of release for 100 quanta ($z = -5$, $\sigma_z^2 = 2$). *b*, Simulated distribution of quantal contents (- - -) and the binomial prediction (———) with parameters derived from the ean and variance of the simulated distribution.

Is it possible to establish that the quantal probabilities are not equal? In general, this is not possible for moderately sized data sets, but in special circumstances it should be possible to record quantal contents on single trials that exceed the estimated value of *n*. Such a result is strong evidence against the validity of binomial statistics, and has been observed at the crayfish neuromuscular junction[8].

The results are clear. Should the release probability for individual quanta be distributed about a mean value, instead of having no variance, then the application of binomial analysis is unjustified even if the considerable practical difficulties involved in the estimation of quantal content can be overcome. Thus, in order to assess the statistics of transmitter release, it is essential to estimate the distribution of the release probabilities. Without this information it is difficult to see how a meaningful analysis can be achieved.

We thank David Attwell, David Eisner, Dr John Iles, Dr Julian Jack and Dr Denis Noble for reading and criticising the manuscript. S.B. is an MRC scholar.

Replication of EBV in epithelial cells during infectious mononucleosis

INFECTIOUS mononucleosis is caused by primary infection with the Epstein–Barr virus (EBV)[1,2]. This virus is generally held to be trophic for B lymphocytes[3–6], but only latently infected cells expressing a nuclear antigen (EBNA)[7] have been found among circulating lymphocytes during infectious mononucleosis[8]. In spite of this, EBV is present in the oropharyngeal secretions of most patients with infectious mononucleosis, and virus continues to be shed in many normal persons for extended periods[9,10]. The source of this virus, a cell type which freely permits replication of EBV, has never been identified. An intriguing link has recently been advanced between EBV and the malignant epithelial cells of undifferentiated carcinoma of the nasopharynx. Patients with this malignancy maintain high titres of antibodies to the virus[11]. The tumour itself, which consists of malignant epithelial cells with many infiltrating lymphocytes, contains the EBV genome[12]. The EBV genetic material is in the malignant epithelial cells[13,14], however, and not in the infiltrating lymphocytes which are predominantly T cells. Although superinfection of nasopharyngeal carcinoma cells with EBV leads to the expression of specific early viral antigens[15], these cells, like B lymphocytes, are only latently infected *in vivo*. The primary cell type infected by EBV probably occupies a pivotal position in the pathogenesis of both infectious mononucleosis and nasopharyngeal carcinoma. We report here evidence directly from human material that EBV replicates in epithelial cells of the oropharynx.

Patients with infectious mononucleosis were selected on the basis of a compatible clinical syndrome, a positive 'Monospot test' (Ortho-Diagnostics, Inc.) and high antibody titres to EBV early antigen (EA) and EBV viral

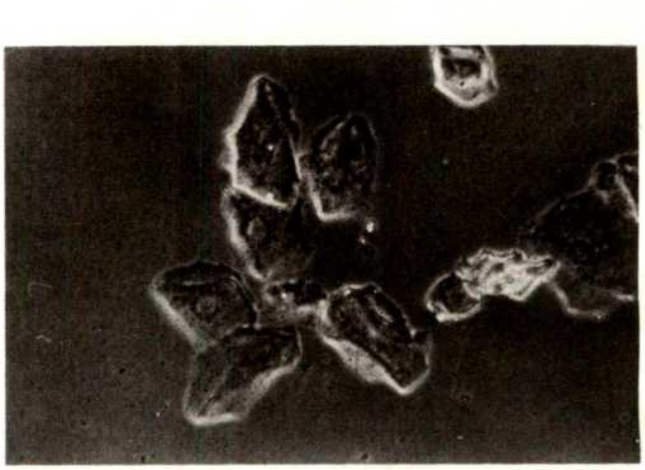

Fig. 1 cRNA–DNA *in situ* cytohybridisation of oropharyngeal epithelial cells from an EBV-antibody negative donor. 8×10^5 c.p.m. ^{3}H-cRNA (specific activity 1×10^7 c.p.m. μg^{-1}) was hybridised under coverslips as described[19,20] for 22 h at 66 °C. Slides were then washed four times in NaCl 0.3 M, sodium citrate 0.03 M (2X—SSC), treated with RNase 20 μg ml^{-1} for 1 h at 37 °C, washed again four times with 2X-SSC, dipped twice in 70% ethanol and then twice in 95% ethanol. Kodak Nuclear Tract NTB2 emulsion was used for autoradiography; exposure was for six weeks at −20 °C. In this specimen, which did not contain EBV, a few scattered grains are seen over each of several epithelial cells. (Unstained, phase contrast, × 475.)

capsid antigen (VCA) (ref. 16). Throat washings obtained by gargling with phosphate-buffered saline solution (PBS) were centrifuged at low speed; the supernatant fluids were passed through a 0.45-μm filter and stored at −70 °C in 10% foetal calf serum. Specimens were tested for EBV by an assay based on stimulation of DNA synthesis in human umbilical cord lymphocyte cultures as described previously[17]. Those throat washings which gave maximal stimulation of thymidine incorporation at 37 d of culture were selected for *in situ* cytohybridisation with EBV-specific complementary RNA (cRNA). Previous efforts to demonstrate EBV-infected cells in oropharyngeal material by indirect or anticomplement immunofluorescence techniques had failed due to intense nonspecific fluorescence.

Centrifugation of each throat washing yielded readily identifiable epithelial cells. The cell pellets were washed twice in PBS, resuspended in ice-chilled methanol–glacial acetic acid (3 : 1) for 5 min and fixed to glass slides for *in situ* cytohybridisation. EBV DNA was purified[18] and EBV-specific ^{3}H-labelled cRNA was synthesised and hybridised as described previously[19,20] to cell smears prepared from specimens known to contain EBV. Cells from a donor without serological evidence of previous EBV infection were also tested. After extensive washing and RNase treatment, hybridised cRNA was demonstrated by autoradiography[19].

Cells from the EBV-negative donor demonstrated a low background of grains diffusely scattered over numerous epithelial cells (Fig. 1). Specimens known to contain transforming virus presented an entirely different picture. The number of grains over almost all epithelial cells was higher than in the control preparations (Fig. 2*a*, *b*). Much more striking, however, was the appearance of dense accumulations of grains over a minority of epithelial cells, often seen in close proximity to other cells which hybridised far less of the EBV-specific cRNA (Fig. 2*a*). The density of grains was uniform over most of these EBV-containing cells, but occasionally there were denser accumulations of grains over the nucleus (Fig. 2*b*).

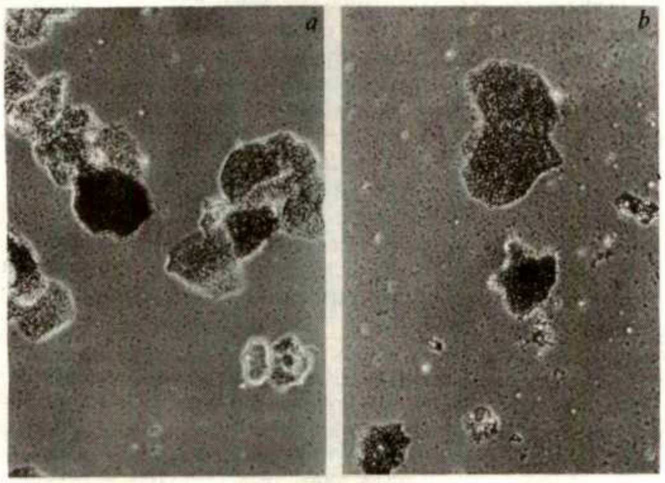

Fig. 2 *a*, Cytohybridisation of oropharyngeal epithelial cells from a patient with infectious mononucleosis and mild pharyngitis. Anti-EA was 1:160 and anti-VCA was 1:160; supernatant fluid from this throat washing resulted in a sevenfold stimulation of thymidine incorporation by cord lymphocytes after 37 d of culture. Note one cell over which there is a dense accumulation of grains while adjacent cells have hybridised relatively little EBV-specific cRNA. *b*, Cytohybridisation of oropharyngeal cells from a second patient with infectious mononucleosis and moderately severe tonsillopharyngitis. Anti-EA was 1:40 and anti-VCA was 1:160; supernatant fluid resulted in fivefold stimulation of cord lymphocytes. Several EBV-infected cells are present; in one, grains are concentrated over the cell nucleus. (*a*, *b*, Unstained, phase contrast, ×674.)

The number of grains over the most positive of these EBV-infected cells was equivalent to that seen over P3HR-1 cells that replicate EBV DNA and produce virus (Fig. 3). As the sensitivity of *in situ* cytohybridisation is rather low (about 60 EBV genomes per cell)[20], the results indicate a very high number of EBV genomes per positive epithelial cell. This itself constitutes strong evidence not only for infection with EBV but also for *in vivo* replication of the virus.

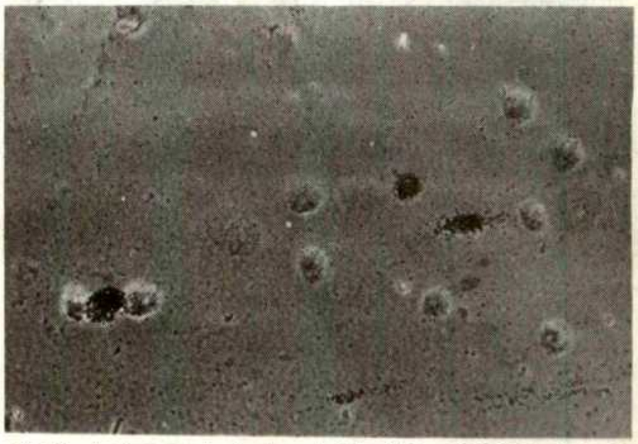

Fig. 3 A virus-producing lymphoid cell line (P3HR-1), derived from African Burkitt's lymphoma, which was hybridised at the same time as the oropharyngeal cells. Four EBV-producing cells can be seen, whereas other, latently infected lymphoid cells did not hybridise appreciable amounts of cRNA. The density of grains over the virus-producing cells is equivalent to that over EBV-infected epithelial cells in Fig. 2*a* and *b*. (Unstained, phase contrast, ×674.)

Since there is virus in the throat, virus might adsorb on to epithelial cells. This would give fewer grains, however, not localised on the nucleus and not spare adjacent cells. To control for this possibility, normal epithelial cells were exposed to a filtrate of a mononucleosis throat washing before cytohybridisation. This exposure produced little adsorption of virus as disclosed by hybridisation, even though the filtrate contained transforming virus and in spite of the presence of EBV-infected epithelial cells in the original mononucleosis specimen (Fig. 4).

When stained with methylene blue–basic fuchsin, the EBV-infected cells showed the small centrally placed nuclei and abundant cytoplasm typical of epithelial cells. There was no obvious cytopathic effect, but morphology following NaOH denaturation was less than optimally preserved.

Our results indicate that EBV infects and replicates within epithelial cells during the course of infectious mononucleosis. This observation answers several longstanding questions. It suggests that the epithelial cell is the source of the virus found in throat washings, consistent with the observation that virus shedding can occasionally be localised in the anterior oropharynx where lymphoid tissue is scant, but epithelium abundant, rather than the posterior pharynx and tonsillar areas[10]. Infection of the oropharyngeal epithelium may also account for the intense pharyngitis often seen in infectious mononucleosis. Virus presumably reaches the tonsils by way of the epithelium, where infection and transformation of the B lymphocyte occurs[21]. The transformed B lymphocyte then evokes a cytotoxic cellular response, characterised by the atypical lymphocyte which may by itself be largely responsible for the systemic manifestations of the disease[22,23].

It has been difficult to reconcile the presumed lymphotrophic nature of EBV with the presence of EBV DNA in the malignant epithelial cells of nasopharyngeal carcinoma. Although the lymphocyte has long been considered

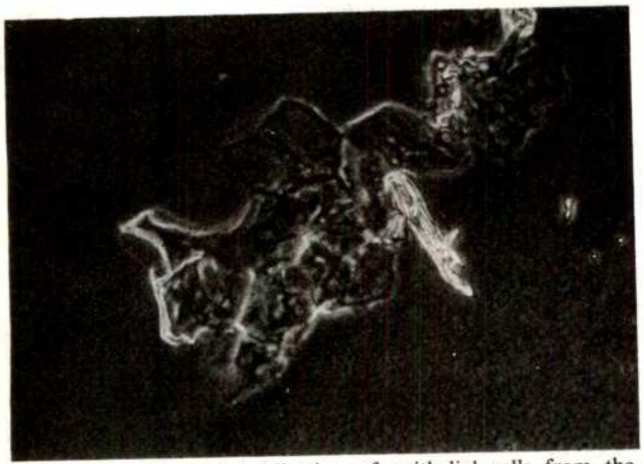

Fig. 4 *In situ* cytohybridisation of epithelial cells from the throat of a patient without antibodies to EBV after adsorption with supernatant fluid from a throat washing that contained transforming virus. Cells collected from the normal donor were washed twice in PBS and resuspended in the supernatant filtrate from the mononucleosis patient described in Fig. 2*a*. The normal cells were allowed to adsorb virus for 2.5 h at 4 °C, washed twice in PBS, fixed in methanol–acetic acid and processed for cytohybridisation as described in Fig. 1. There are only scattered grains over the cluster of epithelial cells. (Unstained phase contrast, ×674.)

the primary cell infected with EBV, it may well be that the primary cell is instead the epithelial cell. No other cell type has been shown to support EBV replication *in vivo*. Epithelial cell infection may be predominantly lytic and productive. Occasionally, however, perhaps influenced by genetic factors, there may be arrest of viral DNA replication, formation of EBV DNA episomes[24], and transformation of the epithelial cell. Such a transformed cell may be the progenitor of nasopharyngeal carcinoma.

We thank Marie Harris, Carolyn Smith, David Crews and Henry Kopf for technical assistance; Dr Daniel Vaughn and others of the University of North Carolina Student Health Service for referral of the patients studied; and Dr K. Blanton for assistance in preparing photomicrographs. This study was supported in part by grants awarded by the National Cancer Institute. S.M.L. is the recipient of a National Research Service Award.

5′-Terminal nucleotide sequences of polio virus polyribosomal RNA and virion RNA are identical

POLIO virus is a positive strand virus; it has a mRNA of the same 5′ to 3′ polarity and size as its virion RNA (ref. 1). It also has a protein covalently linked to its 5′-terminal end forming a 5′-terminus of protein–pU–U–A–A–A–A–C–A–Gp (refs 2, 3). This contrasts with other viral RNAs that either have di- or triphosphate 5′-termini (negative strand RNAs)[4–6] or $m^7G^{5'}ppp^{5'}N(m)p$ . . . termini (most positive strand RNAs)[7,8]. The 5′-linked protein on poliovirion RNA is also found on at least two-thirds and perhaps all of the nascent chains of the replicative intermediate isolated from infected cells[3]. This suggests that the protein is linked to the RNA at a very early stage of replication, perhaps as a primer during the initiation of RNA synthesis[2,3]. The 5′-terminus of polio virus polyribosomal RNA lacks the protein and instead terminates in pUp . . . (refs 9, 10). Thus, it is possible that the protein initially present on the newly synthesised RNA chains is cleaved from that fraction of the RNA molecules destined to become mRNA. To determine the nucleotide sequence relationship between the polio virus RNAs containing and lacking the protein, we have isolated and sequenced the 5′-terminus of poliovirus polyribosomal RNA. We show here that its nucleotide sequence is identical to that of the 5′-terminus of virion RNA.

To identify the 5′-terminal oligonucleotide of poliovirus polyribosomal RNA we used the characteristic that distinguishes it from all other oligonucleotides in the RNA, the presence of a pUp residue. The total mixture of RNase T_1 oligonucleotides was fractionated by ionophoresis on cellulose acetate in the first dimension and homochromatography on polyethyleneimine (PEI)–cellulose plates in the second dimension[11,12] (Fig. 1*a*). To find the 5′-oligonucleotide, regions of the fingerprint were scraped from the PEI–cellulose plate and digested with RNases T_1, T_2 and A. The products were separated by paper electrophoresis at *p*H 3.5 (ref. 11). Only one spot on the fingerprint gave rise to pUp which was identified by its characteristic mobility just slower than orthophosphate[3]. An arrow indicates the pUp-containing spot in Fig. 1*a*. The rest of the regions analysed gave rise only to 3′-monophosphates. The identification of the pUp-containing oligonucleotide as the 5′-terminus of polyribosomal RNA is supported by its absence from the fingerprint of virion RNA (Fig. 1*b*, arrow). For virion RNA, the protein-linked 5′-terminal T_1 oligonucleotide would have been excluded from the second dimension because of its slow mobility in the first dimension[3].

The intensity of the pUp-containing spot was weaker than that of the neighbouring spots suggesting that it either was present in a submolar amount or that it contained fewer phosphates than the adjacent oligonucleotides. The two oligonucleotides to the right of the pUp-containing spot were determined to be about 18 and 20 nucleotides long. This was based on a quantitation of the RNase P_1 digestion products relative to the radioactivity in the

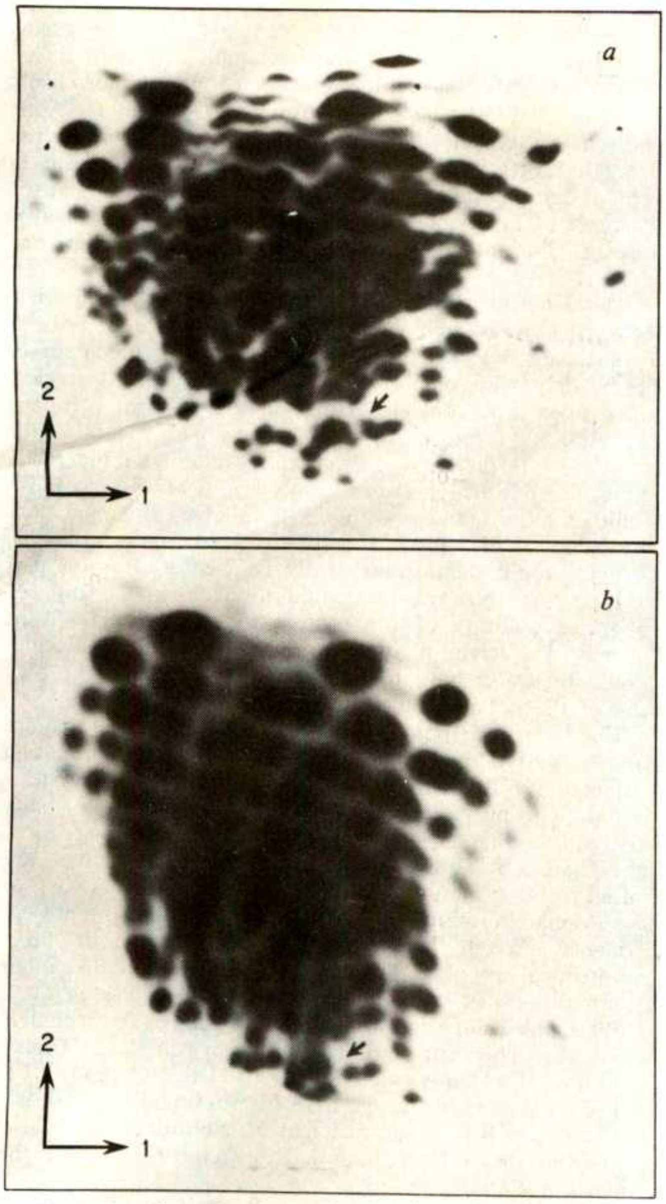

Fig. 1 Two-dimensional separation by electrophoresis and thin-layer chromatography of RNase T_1 oligonucleotides derived from polio virus polyribosomal and virion RNA. Polio virus-specific RNA labelled with ^{32}P-orthophosphate (New England Nuclear) was prepared by infecting actinomycin D-treated HeLa cells in suspension with polio virus type 1 as described previously[3,9]. RNA from purified virions labelled with ^{32}P (collected 6 h post-infection) was prepared by extraction with sodium dodecyl sulphate–phenol (SDS–phenol) and purified by sucrose gradient centrifugation as described previously[17]. Polio virus polyribosomal RNA was prepared from cells collected 3.5 h post-infection as described previously[9,16]. In summary, a cytoplasmic extract was taken and the polyribosomes collected on a sucrose cushion[17]. The polyribosomal RNA was precipitated with 2 M LiCl in the presence of 0.5% SDS at −20 °C. The precipitate was extracted three times with phenol–chloroform–isoamyl alcohol (25:24:1) and the RNA was recovered by ethanol precipitation and centrifugation. The RNA was further purified by oligo(dT) cellulose chromatography and sucrose gradient centrifugation. The peak fractions of 35S RNA were pooled and the RNA wax precipitated by two volumes of ethanol. Yields of between 1 and 3×10^7 c.p.m. (Cherenkov radiation) of ^{32}P-labelled polyribosomal RNA were regularly obtained from 4×10^8 cells and 60 mCi ^{32}P-orthophosphate. Purified polyribosomal and virion RNAs were digested with RNase T_1 for 30 min at 37 °C in 3 µl of 10 mM Tris, *p*H 7.4, and 1 mM EDTA containing 10 µg of RNA and 200 U ml^{-1} of T_1 (Calbiochem). The resulting oligonucleotides were subjected in the first dimension to electrophoresis on Cellogel strips (Chemeton, Milan) at 2,500 V for 70 min at *p*H 3.5 (ref. 11). Separation in the second dimension was by chromatography on plastic-backed polyethyleneimine–cellulose thin-layer plates (20×20 cm, Brinkmann Instruments)[11,12]. Homomixture C (ref. 11) digested for 2 min with 1 M KOH was used for the second dimension. *a*, Autoradiogram of a fingerprint of polio virus polyribosomal RNA; *b*, autoradiogram of polio virus virion RNA. In (*a*) the arrow indicates the position of the pUp-containing 5′-terminal oligonucleotide and in (*b*) the arrow indicates the absence of the spot from the virion RNA. Different batches of homomixture were used in (*a*) and (*b*).

5′-GMP. Correction for the unequal labelling of the four monophosphates was done as described previously[3] and in the legend to Table 1. As shown below the length of the 5′-terminal oligonucleotide is only 9 nucleotides (10 phosphates). Apparently the additional 5′-phosphate in the terminus substantially retards the mobility of the oligonucleotide during homochromatography.

Table 1 Ribonuclease A and U_2 products derived from the 5′-terminal oligonucleotide of polio virus polyribosomal RNA

	Product	Yield*
RNase A†:	A–A–A–A–Cp	1.0
	A–Gp	1.0
	pUp	0.7
	Up!‡	0.9
RNase U_2§:	[pUp, Up, Cp, $(Ap)_n$]	
	[pUp, Up, $(Ap)_n$]	
	A–Ap	
	C–Ap	
	Gp	
	Ap	

*The yield of RNase A products was calculated relative to A_4C. Corrections for unequal labelling of the four nucleoside monophosphates were done[3]. The ratios of the radioactivity of the 5′ monophosphates to that of the 3′ monophosphates were found to be 1.0 for CMP, 0.8 for AMP, 0.6 for GMP and 1.6 for UMP. In the case of Gp, where the nearest neighbour was unknown, a specific activity of 1.0 was used for the phosphate.

†Digestion conditions were: 30 min at 37 °C in 5 µl of 20 mM Tris, *p*H 7.5, and 2 mM EDTA, containing 15 µg of yeast RNA (Sigma) and 7.5 µg of RNase A (Worthington).

‡All the uridine monophosphate was recovered as 2′,3′ cyclic UMP.

§Only the composition of the two largest RNase U_2 products is indicated because exact sequences were not determined. The U_2 digestion conditions were: 2 h at 37 °C in 10 µl of 15 mM sodium acetate, *p*H 4.5, and 1 mM EDTA containing 0.01 U of U_2 (Calbiochem). In these conditions the U_2 products presumably contained 2′,3′ cyclic monophosphate termini.

Further purification of the oligonucleotide was required for sequencing purposes and was accomplished by elution of the oligonucleotide and fractionation on a two-dimensional polyacrylamide gel[6,13]. A major component migrated in the first dimension together with the bromophenol blue dye and in the second dimension slightly faster than it (Fig. 2). A few faint spots representing contaminating oligonucleotides from the first two-dimensional fingerprint could also be observed. Only the major spot contained pUp and therefore must have been the 5′-terminal T_1 oligonucleotide. Molar yields of secondary digestion products (Table 1) established the purity of this oligonucleotide.

To determine the sequence of the oligonucleotide, it was eluted, digested with RNase A or RNase U_2, and the products were separated by ionophoresis on DEAE-paper at *p*H 3.5 (ref. 11). RNase A digestion gave rise to four products, which were identified as A–A–A–A–Cp, A–Gp, pUp, and Up! on the basis of their migration relative to marker oligonucleotides and subsequent base composition analysis. All four products were present in approximately equimolar amounts (Table 1). The order of the RNase A products was established from the RNase U_2 digestion products (Table 1). The product C–Ap showed that the RNase A products A–A–A–A–Cp and A–Gp must have been linked in that order. The Up residue therefore must have been between pUp and A–A–A–A–Cp and we conclude that the sequence of the total oligonucleotide is pU–U–A–A–A–A–C–A–Gp. The sequence of the two large RNase U_2 products must have been pU–U–A–A–A–A–C–Ap and pU–U–(A_n)–Ap considering the RNase A digestion products. These products are consistent with the known specificity of RNase U_2 (ref. 11) and confirm the sequence. Thus, the nucleotide sequences of the 5′-terminal T_1 oligonucleotides from polio virus virion and polyribosomal RNA are identical, but the polyribosomal RNA lacks the protein at its 5′-end. We have also analysed the complete RNase T_2 products derived from the oligonucleotide on a two-dimensional thin-layer chromatography system[14] and found no evidence for any modified bases in the oligonucleotide (data not shown).

We have described a method for purifying to homogeneity the 5′-end T_1 oligonucleotide from polio virus polyribosomal RNA. Although the oligonucleotide contains only nine bases, its 5′-phosphate causes it to migrate slowly during homochromatography through PEI–cellulose positioning it in the region of the fingerprint where it is detectable as an individual spot. To purify it sufficiently for sequencing, further fractionation was needed and the two-dimensional electrophoretic system of De Wachter and Fiers[13] provided the needed resolution. This system fractionates mainly on the basis of base composition and length and would be expected to show less effect from the 5′-phosphate.

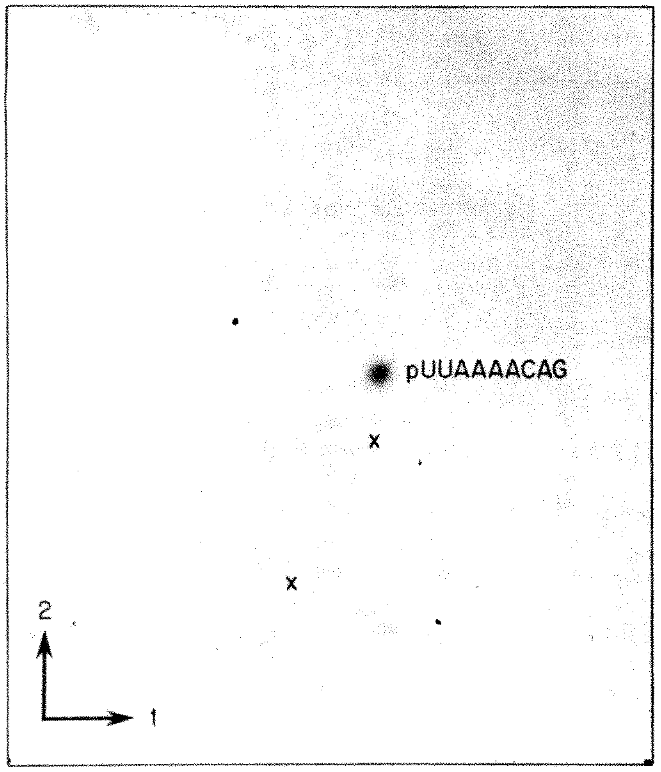

Fig. 2 Purification of the 5′-terminal oligonucleotide of polio virus polyribosomal RNA by two-dimensional gel electrophoresis. The pUp-containing T_1 oligonucleotide from the PEI–cellulose plate (Fig. 1*a*) was eluted with triethanolamine bicarbonate and fractionated by two-dimensional polyacrylamide gel electrophoresis as described previously[6,13]. The first dimension (10% acrylamide, 6 M urea, *p*H 3.5) was run until the bromophenol blue dye had migrated 20 cm. The second dimension (21.8% acrylamide in Tris-citrate buffer, *p*H 8.0) was run until the bromophenol blue dye had migrated 8 cm. The upper × indicates the position of the bromophenol blue dye and the lower × that of xylene cyanol. The sequence of the 5′-terminal oligonucleotide is as indicated.

The replicative intermediate isolated from polio virus-infected cells contains as an average about six growing strands[15]. Quantitation of the protein–pUp in these chains indicated that at least two-thirds contain a protein linked to their 5′-end[3]. Since mRNA is infectious[3], it most likely contains all of the genetic information in virion RNA. It is therefore unlikely that the polyribosomal RNA is derived from a larger precursor molecule by any mechanism in which one or more 5′-terminal nucleotides are lost by cleavage. This conclusion is supported by the identity of the 5′-terminal nucleotide sequences in virion and mRNA.

These considerations suggest that initiation of polio virus RNA synthesis must occur by one of three possible mechanisms: (1) the 5′-terminal protein or a precursor of it, possibly with one or several covalently-linked nucleotides (e.g. protein-pU_{OH}), could act as a primer in the initiation of synthesis of all strands. Subsequently, the protein would be cleaved from that fraction of the RNA molecules destined to become mRNA. (2) RNA synthesis could initiate *de novo* with UTP, followed by rapid condensation of the protein with all RNA molecules. The protein would then subsequently be cleaved from a part of them. (3) RNA synthesis could initiate as in (2), followed by rapid addition of the protein to only a part of the strands. The triphosphate end on the rest of the molecules would then also have to be modified to generate the pUp end of the polyribosomal RNA.

The latter two possibilities seem unlikely. They require that a pyrimidine triphosphate should be the initiating nucleotide. But, virtually all known RNA synthetic systems initiate with purine triphosphates[16]. Furthermore, possibility (3) requires that an enzyme cleave off the two 5′-terminal phosphates; in other systems where triphosphates are initiators the mature molecule retains either a di- or triphosphate terminus. Therefore we believe that the present evidence strongly favours possibility (1) but until direct biochemical proof of the model is provided the other alternatives must be considered possible.

Botanical dimension in Darwin's thinking

R. H. Richens

Darwin and His Flowers: The Key to Natural Selection. By Mea Allan. Pp. 318. (Faber and Faber: London, 1977.) £6.95.

It remains obscure why evolution became scientifically respectable just when it did. Heritable variation at the varietal level was well known and accepted by nurserymen, animal breeders and biologists. The notion of macroevolutionary change was also in the air, as purveyed by Lamarck, Chambers and Charles Darwin's grandfather Erasmus, although less scientifically respectable. Malthus' essay had been widely read. It was not even the case that a vast body of cumulative evidence had to be assembled to vindicate the notion of macroevolution, and it seems that Wallace only required three days to excogitate the theory that Darwin laboured over for so many years.

Perhaps what had been lacking till 1859 was a protagonist in the right club, namely the small group of biologists accepted by themselves and by the general public as representing the forefront of validated scientific thinking. Neither Erasmus Darwin, Chambers nor Wallace were in this club. Charles Darwin, in spite of his lack of formal training, was.

From the point of view of the history of science, then, it becomes more relevant to enquire what led Darwin to sponsor evolution than to ask at what stage the evidence pointed that way. Miss Allan now provides us with some new perspectives. In the course of a very well illustrated account of Darwin's botanical activities, she shows how greatly Darwin was taken up with plants, even though his formal botanical qualifications were thin.

It is clear that Darwin was greatly moved by his encounter with equatorial forest. Possibly, no botanist is most perceptive in his native environment. It is notorious how botany still retains clear evidence of its temperate origins and how potently a small dose of the tropics contributes to theoretical advancement. On the other hand, one can suppose that familiarity with tropical vegetation can be as soporific to its denizens as familiarity with temperate vegetation is to its. It is also clear from Miss Allan's book that plants attracted Darwin as research material, not only as exhibiting the operation of natural selection, but as doing so without the theoretical complication of "willed" activity.

Miss Allan presents her material in roughly chronological order: Darwin's childhood, Edinburgh and Cambridge, the voyage of the Beagle, the *Origin of Species,* his researches on the fertilisation of orchids, climbing plants, plant variation under domestication, insectivorous plants, cross- and self-fertilisation, and heterostyly. Darwin's work is presented very largely in his own terms and in sufficient detail to illustrate his remarkably acute power of observation and experimental ingenuity.

The chief value of Miss Allan's book, beside the pleasure of just looking at it, is the re-orientation that it suggests for the interpretation of Darwin's thought. The botanical dimension has certainly been undervalued in the past. In detail, however, Miss Allan cannot be our guide. Neither her geology—coprolites as fossil excreta—nor her evolutionary and genetic theory—largely presented in the semi-Lamarckian, pre-Mendelian categories of Darwin's later writings—has been brought up to date.

When it comes to personal interpretation, Darwin becomes unreal; the man has become a scientific hero figure with the inevitable distortions that this produces. Her remarks on Darwin's "illness" are trivial. But one imagines that Miss Allan makes no pretensions in these areas. What she has done, and done well, is to present a vivid picture of the role of plants in Darwin's scientific life, and it was Darwin himself who wrote that "a traveller should be a Botanist, for in all views plants form the chief embellishment". ☐

Continuing Newtonian disputes

The Correspondence of Isaac Newton. Volume 6: 1713–17–18. Edited by Rupert A. Hall and Laura Tilling. Pp. xxxviii+499. (Cambridge University: Cambridge and London, 1976. Published for the Royal Society.) £25.

The core of this sixth volume of the Newton correspondence is made up of a collection of letters and documents relating to the controversy between Newton and Leibniz over the calculus, the commencement of which was noticed in the previous volume. Only a few of these letters and documents are from Newton himself, although some of these are of great interest, such as the hitherto unpublished No. 1053*a.* On the British side the most common correspondent is Newton's indefatigible champion John Keill, and on the continental side it is Leibniz himself and Johann Bernouilli, with the Italian Conti—eventually a proselyte to the Newtonian camp—acting as intermediary. The editors speculate how Newton might have spent his time if he had not been involved in this controversy with Leibniz. They might equally have speculated how differently things could have turned out if the controversy had never arisen in the first place, or at any rate had not become envenomed up to the point that British mathematicians effectively cut themselves off for more than a century from the main stream of continental mathematics. It was a strange nemesis that Newton, who by his work in optics, and in the physical, astronomical and philosophical aspects of the *Principia,* had made so vast a contribution both to scientific progress and scientific attitudes in the eighteenth century, and had raised the prestige of British science so high, should have exerted through his mathematical attitudes and techniques so retrograde an influence on British mathematics and mathematical physics in the same century.

This volume witnesses the *dénouement* of the longstanding Newton/Flamsteed controversy in which Flamsteed finally had the better of Newton, largely it seems as a result of the eclipse of certain of Newton's supporters after the accession of George I in 1715. Flamsteed, who now had friends at court, greeted this change of power with glee (letter No. 1151) and rightly anticipated that it would transform his relations with Newton and the Royal Society over the question of the contentious *Historia Coelestis*. In the event Newton and the referees were forced to call off their campaign against Flamsteed to whom the remaining copies of the *Historia Coelestis* were returned—mostly for burning—together with the manuscripts of the observations on which the work itself had been based, and which Flamsteed then used to prepare his own version of the *Historia Coelestis,* published by his wife some years after his death.

A surprising feature is the absence of any letters between Newton and Clarke relating to the latter's famous controversy with Leibniz although this fell entirely within the span of the present volume. As the editors suggest, this could simply have resulted from Clarke's intimacy with Newton and the fact that they both lived in London, although it should not be assumed that Newton played the same sort of role in the Clarke/Leibniz controversy, as in the controversy over the calculus.

Cotes' letter of 22 December 1713 to Newton (No. 1029) marks the dismal end to the magnificent correspondence relating to the preparation and publication of the second edition of the *Principia.* Whatever the reason, resentment at Newton's failure to thank him for his vast unpaid labours on the *Principia,* or increasing ill health—he was to die young in June 1716—Cotes coldly rejected all the corrigenda and addenda suggested by Newton in a previous letter. As for some 20 additional errata listed by Newton in the same letter, Cotes had noticed some of them for himself, but had foreborn to enter them in his own list of errata lest he should appear "too diligent in trifles". He ends his letter with a final implicit reproof by pointing out that he had himself silently corrected some hundreds of errors without troubling to acquaint Newton of their existence.

The standard of editing maintains the high level of previous volumes and there is an excellent introduction including a very helpful survey of the controversy over the calculus. An unfortunate omission, however, is any reference in the page opposite the list of contents to the late J. F. Scott's editorship of Volume 4 of the Newton correspondence. Nor do all the footnotes relating to mathematical questions have that luminous clarity which one is entitled to expect. This I found particularly true of note 1 to Newton's notes on Leibniz's 'Tentamen' (letter 1069*a*). This work of Leibniz certainly provides good justification for Voltaire's quip that "Leibniz is come to confuse the sciences" but unfortunately the footnote itself compounds this confusion. Thus it is misleading to say that the theory of Leibniz is "congruent mathematically with that of Newton in the *Principia*" unless by congruent is meant that Newton and Leibniz arrived by entirely different mathematical methods at the same inverse square result for the radial force for motion in an ellipse. Nor is it entirely true that the difference between the two treatments "lies in the *physical* interpretations of Newton and Leibniz". For although it is true that Leibniz posits a miraculous *ad hoc* 'harmonic' vortex to account for the circulatory motion of a planet in conformity with Kepler's second law, nevertheless a careful examination shows that this vortex plays no part whatsoever in the actual mathematical argument in which the one physical factor is the assumption that the force directed towards the focus will be measured—for a given time interval—by the deviation between the actual curved path and the inertial path along the tangent or approximating cord. It is extraordinary that Leibniz should have hit on this notion —one of the most profund physical insights in the *Principia*—before reading the *Principia* itself.

J. W. Herivel

J. W. Herivel is Reader in History and Philosophy of Science at Queen's University, Belfast, Northern Ireland.

Illuminating mental darkness

Light and Life. By Lars Olof Björn. (Hodder and Stoughton: London, Sydney, Auckland and Toronto, 1976.) Hardback £3.45; paperback £1.75.

As its title implies, this small book seeks to cover a vast field. All situations where light interacts with living organisms provide a subject for discussion in this book. It begins very naturally with photosynthesis and then moves into the animal kingdom for such topics as bioluminescence and vision. Photoperiodism and spatial orientation with respect to light, influence both animals and plants. There remain some essentially anthopocentric subjects—namely, suntan, artificial illumination and photochemical smog.

The book is based on the original Swedish edition, but some of the later chapters are new additions. It has been well translated and reads very freely. The level is about that of *Scientific American* and, like that journal, it relies heavily on simplified diagrams for the communication of information. Technical detail and jargon are avoided and the emphasis is essentially on readability. This, coupled with its accurate, full and up-to-date content, make it the sort of book one can pick up and read cover to cover. It will appeal most especially to sixth-formers and first-year undergraduates but should, and undoubtedly will, also be read by more advanced students and researchers.

When a small book attempts to cover so much it is not difficult to find gaps. A surprising one is the potential of solar energy for space and water heating and energy farming. One could also criticise the inevitable shallowness of parts of the text. It is not a work of reference to which one might resort for a detailed exposition of, say, photorespiration in C−3 plants or phototaxis in *Euglena.* But at least such topics are mentioned and the basis of their interest and importance is adequately conveyed. The provision of a carefully selected further reading list amply covers the needs of the student whose interest has been fired and who needs to delve deeper. Like the Sun god, Aton, to whom this book is dedicated, Professor Björn should succeed in illuminating the mental darkness of many.

P. D. Moore

P. D. Moore is Lecturer in Plant Sciences at King's College, University of London, UK.

Computer image processing

Digital Image Restoration. By H. C. Andrews and B. R. Hunt. Pp. xviii+238.) Prentice-Hall International: Englewood Cliffs, New Jersey, and Hemel-Hempstead, UK, 1977.) £19.95; $31.75. *Digital Picture Analysis.* Edited by A. Rosenfeld. Pp. xiii+351. (Springer: Berlin and New York, 1976.) DM72; $29.60. *Image Science Mathematics.* Edited by C. O. Wilde and E. Barrett. (Western Periodicals: North Hollywood, California, 1976.) $37.50.

THESE three volumes—a textbook, a set of essays ranging from high energy physics to cytology, and a collection of contributions to a highly specialised symposium—give a vivid idea of what is happening in computer image processing and of the directions that the subject is likely to take in the near future, although the very new tse computers (D. H. Schaeffer and J. P. Strong, *Proc. IEEE*, **65**, 129–138, 1977) are not discussed.

The textbook, by Andrews and Hunt, is an extremely useful account of the present state of digital image processing, from a mathematical standpoint; it is very much more than a revised edition of Andrews' earlier text on a similar subject (*Computer Techniques in Image Processing*, Academic: New York and London, 1970), for the material has developed and the points of emphasis changed so rapidly that a completely new text has been written. It is clear and carefully organised; the numerous pitfalls and still unsolved problems are signposted; the notation is easily readable; and in regions where tempers have tended to fray in the past, the authors remain commendably objective, their assessment of digital against optical restoration being a good example. The book is divided into three parts: an introduction, covering image formation, recording and models; two chapters on degradations and determination of parameters characterising these; and four chapters on restoration, covering noniterative methods that use Fourier space, the numerous filters generated by a linear algebraic approach and finally, non-linear algebraic methods. *Digital Image Restoration* has only one direct rival: *Digital Picture Processing* by Rosenfeld and Kak (Academic: New York and London, 1976; for review, see *Nature*, **264**, 142, 1976). Both are excellent and the overlap is less than it might seem from a superficial comparison, for the authors' interests are rather different even though much common ground is covered.

Digital Picture Analysis contains five long contributions: automatic, remote sensor image processing by Haralick; radiographic image analysis by Harlow and Dwyer; image processing in high energy physics by McIlwain; digital picture analysis in cytology by Preston; and picture analysis in character recognition by Ullmann. In contrast to the text by Andrews and Hunt, these essays show clearly the successes and problems of processing real large two-dimensional arrays in very different fields. Pattern recognition, in particular texture analysis, is as important here as image restoration; and inevitably very similar problems occur throughout the various applications. It was an excellent idea to bring this material from such different branches of applied science together in a single volume as the subject is still sufficiently young for extensive cross-fertilisation to be taking place. The essays are of a high standard and are written to be comprehensible to a non-specialist audience.

Finally, we turn to the contributions to the symposium on image science mathematics, held in California in November, 1976. The tone here is very different from that of the other two books under review, for the reader is expected to be conversant with "the story so far", and now ready to read on. There are papers on non-linear restoration, in particular by Frieden on the maximum entropy technique; there are new results on the Karhunen–Loève transform by Jain; Reed *et al.* pursue their work on transforms over finite fields; Kreznar explores the consequences of the lack of a two-dimensional fundamental theorem of algebra; Hunt surveys the (severe) problems of non-linear restoration; Keng and Fu discuss a syntax-directed method of analysing Landsat images; and there are many others. In short, these Proceedings, offset from authors' typescripts, contain much exciting and up-to-date material but they are not for the novice; and furthermore, fuller accounts of the same work are now appearing in the appropriate journals.

P. W. Hawkes

P. W. Hawkes is Maître de Recherches in the CNRS Laboratory of Electron Optics, Toulouse, France.

Comparative immunology

Comparative Immunology. Edited by J. J. Marchalonis. (Blackwell Scientific: Oxford and London, 1976.) £15.50.

THE past 15 years have seen a surge of interest in developmental immunobiology. *Comparative Immunology* provides a timely review of the extensive list of research papers in this field and gives insight into phylogenetic and ontogenetic studies currently in progress in the authors' laboratories. Contributions from more than 20 expert immunologists fit together well to make this a really first-rate, readily-readable review.

As a preface to the chapters on phylogeny of immunity, Nossal outlines the cellular, molecular and genetic basis of the complex immune system found in mammals, and Rosser, drawing attention to evolutionary principles, suggests that lower organisms may well have evolved different forms of defence. This suggestion is, in part, borne out by the chapters that follow, on the evolution of cellular immunity. Thus although Cooper presents evidence that all invertebrates, even the Protozoa, can distinguish self from non-self, and postulates the existence of primordial cell-mediated immunity in annelids and echinoderms, Jenkin concludes that recognition by invertebrate phagocytes is based on a system of serum proteins which, although analogous in function, differ in structure from the immunoglobulins that are unique to the vertebrates. Insight into the physicochemical and biological properties of non-mammalian immunoglobulins can be gained from later chapters.

Ontogenetic aspects of cellular and humoral immunity in amphibians, reptiles, birds and mammals are examined in some detail. Rowlands describes immune responses of prototherian and metatherian mammals and discusses how these studies are relevant to the study of immune development. Du Pasquier's elegant work reveals that amphibians are proving invaluable in elucidating the mechanism of tolerance, the origin of antibody diversity, the role of the thymus and the nature of the T-cell receptor. Furthermore, Cohen illustrates that "Linnaeus' loathsome amphibians" possess an unusual array of immunological phenomena, while Balls and Ruben make central use of these poikilotherms in excellent reviews on the phylogeny of neoplasia and immune reactions to tumours, and on the nature of cell co-operation.

The book should prove invaluable to all immunobiologists wishing to learn in depth about the evolution of immunity in the entire animal kingdom and of the advantages that can be gained by using simple model systems to study central issues in immunology.

J. D. Horton

J. D. Horton is Lecturer in Zoology, at the University of Durham, UK.

Water and aqueons solutions

Liquids and Solutions: Structures and Dynamics. By P. Kruus. Pp. 592. (Marcel Dekker: New York and Basel, 1977.) SFrs. 145.

THIS book is based on a graduate course and seminars, and is intended for physical chemists and people with related interests—for example, engineers and biologists. Certain topics are deliberately omitted—for example, glasses, melts, quantum liquids, liquid metals, and liquid crystals. A feature is the considerable attention given to water and aqueous solutions. These topics are of the greatest interest to other scientists but are often neglected because water (or an aqueous solution) is extremely difficult to handle theoretically. The author does not try to deal with any topic in depth but has produced what amounts to a very interesting series of review articles with a very large number of appropriate references. These will certainly be valuable both to specialist research workers, and to workers in related fields, for many years to come. One is struck both by the author's vast reading, and by his ability to summarise a particular field and put it into proper relation with other fields.

The book is divided into three parts. Part A deals with theoretical approaches: what are the forces between molecules or ions and how do we allow for their effects? Model treatments, distribution function theory and the theory of electrolytes are all summarised with appropriate references, but the reader is always left wanting more. Two chapters on transport properties and molecular motions can only be described as sketchy.

Part B is concerned with experimental studies. We can distinguish between what we can deduce from the equilibrium properties and transport coefficients (chapters 8 and 9), what we can deduce by bombarding the liquid with neutrons or by imparting various forms of energy to it (chapters 10 and 11, and 14–16), and what we can learn by using a typical molecule as a probe in magnetic resonance and spectroscopic studies (chapters 12 and 13). Each chapter has some specific examples of the application of each method. A considerable amount of very interesting material is given, but one would have welcomed a further chapter explaining exactly what sort of information can legitimately be expected from each method. For example, it may seem elementary to the author that because of wavelength considerations, ultrasonic and light-scattering studies tell us nothing about the distribution function but a great deal about critical fluctuations; but such information would be welcome to some of his likely readers.

Part C gives very brief accounts of thermodynamics statistical mechanics, electromagnetics and quantum mechanics. This is the weakest feature of the book. Although over 70 pages are used, these chapters are no substitute for a proper textbook, as the author himself recognises. If these topics are to be treated at all, why not include hydrodynamics also? I would like to have seen these pages used instead in expanding the excellent parts A and B, some chapters of which have quite clearly had to be unduly compressed.

Despite this tactical error, I adhere to my opinion that the author has done a good job in summarising what is now a considerable body of knowledge and that the result will be helpful to research workers. The emphasis on water and aqueous solutions is particularly to be commended at the present time, much of the material given being hard to find elsewhere.

H. N. V. Temperley

H. N. V. Temperley is Professor of Applied Mathematics at University College, Swansea, Wales, UK.

Complexities of intelligence

Intelligence: Nature, Determinants and Consequences. By E. B. Brody and N. Brody. Pp. x+241. (Academic: New York and London, 1977.) $12.50; £8.85.

INTELLIGENCE TESTING has been with us for some seventy years, and the results used—and sometimes misused—for important social and educational purposes during much of this period. From the start, at least two irreconcilable lines of thought about intelligence test scores can be traced. The first was at the outset peculiarly British, initiated by Galton and developed by Spearman, suggesting that there exists a central, inherited general intellectual capacity, fixed and unalterable, and directly measurable by tests. The second, which arose from the work of Binet in Paris, stressed the potentially plastic nature of intellectual functions.

Today, the questions of plasticity of intelligence, the degree of its heritability both within and between groups and races, remain central and controversial. The debate has been sharpened by Jensen's article (1969) which suggested a strong inherited component in the well-attested average negro–white IQ differences, and by revelations in 1974 by Jensen and by others, that some of the major post-War data of Sir Cyril Burt, the arch-hereditarian, were worthless.

The book by Brody and Brody addresses itself to problems such as these, sketching initially a little of the historical background, considering the work of Cattell and Guilford on the structure of the intellect, and outlining the quantitative characteristics of global indices. The relationship between test scores and achievement is reviewed and the respective roles of genetic, biological and social environmental factors as determinants are considered. A critical chapter is devoted to the problems of racial differences, birth order and family size, and the volume concludes with a review of the use of tests in the educational system, in selection and in clinical assessment.

Like many new American books in this field, this volume reflects the radical change which has taken place in recent thinking on what intelligence tests measure, their social and educational applications, and the constellation of variables which affect their results. It is up-to-date, clearly written and indicative of an unusual width and depth of knowledge. Surprisingly, however, it is weak in the section on stability and change in individual intelligence during the lifespan, considering in detail only one major longitudinal study; indeed, it underestimates the amount of relative change occurring in children reared in fairly constant environments. It also pays too little attention to the many careful studies on larger IQ changes following major environmental shifts. Yet the authors are rightly doubtful of "critical period" hypotheses which suggest that only early interventions may be rewarding for the disadvantaged. They fail, however, to spell out in detail the implications for successful interventions, in particular duration and totality.

Here and there, one can fault the authors' statements: for example, the results of the important Dutch Famine Study are open to alternative explanations than the one they favour, and they do not reveal any awareness of this controversy. The omission of an author index and the sketchiness of the subject index are also surprising. All in all, however, this book achieves its aim—a balanced account of the major issues. It will be valuable to those who seek an introduction to understanding these complexities.

obituary

Pehr Edman

Dr Pehr Edman, FRS, died on 19 March 1977, in Munich, at the age of 60. In an eventful and distinguished scientific career on three continents, he was undeniably one of the most influential figures in advancing our understanding of the chemical structure of proteins.

Pehr Edman was born in Stockholm on 14 April 1916. Though his undergraduate training was in medicine, very early on he was attracted to the field of biological chemistry, then in its infancy, and in the 1940s carried out (with U. S. Von Euler and E. Jorpes) some of the earliest work on the chemical characterisation of angiotensin. He later spent a year at the Rockefeller Institute in the laboratory of John H. Northrop, studying the effects of tyrosinase on several proteolytic enzymes.

In retrospect it is difficult to envisage the primitive state of methods for peptide analysis at that time. An amino acid analysis of a protein was a major undertaking; sequence analysis of even a small peptide was a chemical *tour de force*. Pehr Edman clearly recognised the need for beter analytical techniques for proteins, and was to devote almost his whole scientific career to developing them.

He approached this task with thoroughness and attention to detail illuminated by a clarity of thought characteristic of the man. His critical insight was to see that earlier attempts at an end group procedure for peptides by Max Bergmann and Emil Abderhalden could be converted into a sequential degradation procedure by simply substituting sulphur for oxygen in the reagent used. This led to one of the most important, (and most often cited) papers in modern biological literature: 'A Method for the Determination of the Amino Acid Sequence in Peptides' published in *Acta Chemica Scandinavica* in 1950.

From this point Edman's international reputation was established, and he could easily have taken the method as it then was and applied it to structural studies on proteins of biological interest. High honours would have surely and rapidly followed, as they did to others. (Sanger, earlier, and Moore, Stein, Anfinsen and Edelman, later, received Nobel Prizes for their studies on protein structure and function). Pehr Edman typically took a more difficult road. He set out to perfect the sequential degradation method, a task that was to occupy the rest of his life. The way he went about this is in itself a fascinating story. Suffice it to say that in 1967, with a talented colleague in Melbourne, G. Begg, he published in the first issue of the *European Journal of Biochemistry* an article describing an instrument, the 'sequenator,' for the automatic determination of sequences in proteins. This instrument is now produced commercially and is in use in many laboratories around the world. Its availability has vastly accelerated progress in molecular biology. For this work Pehr Edman was awarded in 1971 the Commonwealth Brittania Award, and the rare Berzelius Gold Medal (the eighth awarded this century). In 1974 he was elected to the Royal Society of London.

At a personal level Pehr Edman was an interesting and complex man. Close or intimate relationships were rarely established even by those who worked in the same field or who followed his methods closely. I was privileged to be one of a small number of his students and close associates. These included John Sjoquist, Birger and Margareta Blombäck, Agnes Henschen (later his wife), Frank Morgan, and of course his colleague for fifteen years, Geoffrey Begg. Pehr rarely spoke of personal matters, but it seems that the end of his first marriage in divorce and some disappointments in local recognition and advancement in Sweden may have contributed to his decision to move to Melbourne in 1957 as Director of St Vincent's Hospital School of Medical Research.

Initially this must have been more a self-imposed exile than a positive career decision. The laboratories at St Vincent's prior to his arrival were nonexistent. Apart from the late Professor John Hayden and one or two others, the staff at St Vincent's in 1957 had little idea of the real potential of Edman's work or of his outstanding scientific abilities. As his work had no obvious immediate clinical relevance he was largely ignored by the hospital. Pehr Edman's reserved, not to say withdrawn, personality contributed to this. The end result was that he worked for many years in virtual isolation both from St Vincent's Hospital and with a few exceptions from the Australian scientific community. He gained at least the local reputation of being unsociable and difficult. On the contrary, he was, I believe, a rather shy person who simply did not have the sort of extroverted nature required to make his presence felt in the scientific wilderness of Australia in which he found himself.

To his close associates and friends, and to scientific visitors to his laboratory he was a totally different man—warm, helpful and unfailingly courteous. However, he was uncompromising in his attitude to anything he regarded as scientifically unsound. In his own work he was overwhelmingly competent. He enjoyed working at the bench, designed and made his own instruments and was an excellent glassblower. In the European tradition, the laboratory was run on disciplined lines. No short-cuts or shoddy techniques were tolerated. He put great emphasis on self-reliance and careful use of equipment. At least in the early days in Australia he refused to buy the commercially produced micropipettes of Lang–Levy design. Each was made and calibrated in the laboratory and kept with scrupulous care. Chemicals were never used straight out of the bottle; before each experiment began he would personally carry out a careful redistillation or recrystallisation of the required reagents. His approach was totally professional.

Pehr Edman was a man of cultivation, widely read, interested in music and the arts, and a gourmet cook. At morning and afternoon tea breaks at work his ritual was to sit down, light one of his favourite thin cigars and slowly drink a cup of very strong freshly ground coffee. The conversation, usually unrelated to science, reflected his wide interests and cosmopolitan attitudes.

Though at first he must have felt the scientific and personal isolation in Australia, Pehr grew to love his country of adoption and later became an Australian citizen. He particularly enjoyed fishing and bird-watching, and few scientific visitors from overseas escaped a day-long excursion to Sherbrooke Forest, near Melbourne, to catch a glimpse of the elusive Australian lyre bird.

In 1972 he left Australia for Munich to be head of a new protein chemistry unit at the Max-Planck-Institut für Biochemie at Martinsried. Unhappily he did not long survive in this new venture. He leaves a wife, Dr Agnes

Henschen-Edman, and two young children, Carl and Helena.

Though his career was tragically cut short, he succeeded brilliantly in the task he set himself. One wonders what scientific problem would not have succumbed to Pehr Edman's creative and single-minded endeavours.

H. D. Niall

C. J. Smithells

Dr Colin J. Smithells who died on 25 March 1977, held a variety of posts in the metallurgical field since he graduated in chemistry at Leeds University in 1914.

Immediately after graduation he joined the Army in which he served with distinction throughout the 1914–18 war reaching the rank of Major in the Gloster Regiment, gaining the Military Cross and being mentioned in dispatches.

In 1919 he joined the research staff of the General Electric Company at the new laboratories being set up by Sir Clifford Patterson at Wembley. There he was primarily responsible for the production and fabrication (by the new metallurgical techniques such as powder metallurgy) of the less well-known metals—with particular reference to tungsten and the manufacture of lamp filaments, receiving valves etc. His book *Tungsten* continues to hold the field and other books, such as *Gases in Metals* have established with authority the existing state of knowledge at the time they were written.

He was awarded the degree of DSc. by Leeds University in 1921. While still at GEC in 1937 he developed a Heavy Alloy (of tungsten nickel and copper) particulars of which were first published in *Nature* in 1937.

In 1938 he left the GEC to become General Manager of Lodge Plugs of Rugby where he was concerned with the use of platinum alloys until 1944 when he was appointed Director of Research of the British Aluminium Company. Here he was responsible for the setting up of the Company's new and now well-known Research Laboratories at Chalfont Park in Buckinghamshire.

In 1956 he retired from Chalfont Park to become Managing Director of Magnesium Elekton Limited, which post he held until he finally retired in 1963.

Throughout his working life he devoted time generously to the work of organisations which aimed to benefit the industry and profession of metallurgy. He was, in 1945, a Founder Fellow of the Institution of Metallurgists, of which he was President in 1951–52. In the following year he was President of the Institute of Metals and throughout gave much time to the work of government committees and industrial bodies such as the British Non-Ferrous Metals Research Association and the Aluminium Development Association. In 1949 he edited the first issue of the *Metals Reference Book*, a comprehensive collection of data which he saw through several new editions.

He was outstanding in the profession for his charm of manner and clarity of thought and speech and will be a great loss. He is survived by his wife Mary, two sons and three daughters.

G. L. Bailey

R. N. Singh

Professor R. N. Singh, formerly Head of the Botany Department of Banaras Hindu University, died from heart failure on March 9, 1977. He was internationally recognised as an authority on phycology, to which he contributed much original observation and in which he initiated new lines of research. Especially, he was distinguished for his work on nitrogen fixation by blue-green algae in rice fields, making contributions both to botanical knowledge and practical agriculture. Besides isolating and characterising various nitrogen-fixing species, he was one of the first to study the paddy field as an ecosystem. His use of the simple expedient of enclosing areas of alkaline "Usar" lands, so that ponds form in the rainy season and prolific growth of blue-green algae is encouraged, is a method of reclamation the full potential of which has not yet been realised. This and other work is described in his book, *Role of blue-green algae in nitrogen economy of Indian agriculture* (1961). He also carried out research on the taxonomy, morphology, physiology, radiation biology, genetics and virology of blue-green algae. In the course of this work he produced many mutant strains of blue-green algae, which have interesting implications for our understanding of morphogenesis in these organisms.

R. N. Singh was born on August 2, 1915, in the Deoria district of Uttar Pradesh and was educated at the U.P. College, Varanasi and Even Christian College, Allahabad. He obtained the M.Sc. degree in 1938 at the Banaras Hindu University while working under Professor Y. Bharadwaja. In 1946 he was awarded the D.Sc. of the same University. He worked in several famous laboratories abroad including the Department of Botany, University College London, the Department of Biochemistry, University of Wisconsin (where he participated in the preparation of the first cell-free extracts active in nitrogen fixation), and the Plant Research Laboratory, Michigan State University. He travelled widely and was a familiar figure at international conferences on phycological and limnological topics.

Besides being a creative research worker, Professor Singh was an outstanding teacher of plant physiology as well as phycology and many of his students now hold responsible posts in different parts of the world. He established a well equipped phycological laboratory in the Banaras Hindu University where he trained more than thirty Ph.Ds in various branches of phycology. After retirement he occupied himself with writing on recent developments in the study of blue-green algae. It is to be hoped that these nearly completed works will be published in due course. His sudden death is a sad loss to Indian science and phycology generally. He will be remembered with affection and gratitude by his many friends and students.

P. K. Singh
G. E. Fogg

Eli Lilly

Eli Lilly, former President and Chairman of Eli Lilly and Company of Indianapolis died on 24 January at the age of 91. He was a very remarkable man. From the age of 10 he worked with his father Josiah K. Lilly Senior, in the family business and in 1907 qualified as a pharmaceutical chemist from the Philadelphia College of Pharmacy and Science, where his father also had studied. Thereafter he developed an interest, ahead of his time, in efficiency of production methods, becoming superintendent of the manufacturing division in 1909, general superintendent in 1915, and vice-president from 1920 until 1932 when he succeeded his father as president. He guided the company through the difficult Depression years of the early 1930s and despite the economic downturn no employees were laid off. Under his overall guidance the production of insulin for diabetes was developed in the 1920s, the production of liver extract for pernicious anaemia, and of barbiturates, in the 1930s; and after the war production of penicillins and other antibiotics including erythromycin.

Lilly was a great philathropist. He endowed a memorial laboratory in 1936 at the Philadelphia College of Pharmacy and founded Lilly Endowment, Inc. in 1937 which over the years has given some 250 million dollars to charitable causes. His wide-ranging interests included educational and civic activities, stock-breeding and archaeology. His wife died in 1973 and their daughter in 1970. There are no immediate survivors.

Frank Hartley

announcements

On the Move

S. Sampanthar, Department of Mathematics, University of Salford, to Department of Mathematics, University of Calabar P.M.B. 1115 Calabar, Nigeria on 11 July 1977.

Details of changes of department, sabbaticals, where leave will be taken and so on should be sent to On the Move; there is no charge for this service.

Awards

Charles Earp of Standard Telecommunications Laboratories is the first recipient of the new award, the J. J. Thompson Medal, of the Institution of Electrical Engineers, for his work on communication and radio navigational aids.

W. E. Klinner was the first recipient of the Douglas Bomford Trust Prize from the Institution of Agricultural Engineers for the best technical paper, entitled 'The Field Treatment of Grass for Conservation', presented at the 1976 Annual Conference.

The European Physical Society has awarded the 1977 Hewlett–Packard Europhysics Prize (20,000 S.Fr.) to Professor Walter Eric Spear of the Carnegie Laboratory of Physics at the University of Dundee in Scotland for his work on a special form of semiconductor which is non-crystalline and can be prepared as thin films.

B. Heezen is the recipient of the 1977 Walter H. Bucher Medal for original contributions to the knowledge of the Earth's crust.

P. Richards received the 16th James B. Macelware Award for significant contributions to geophysical sciences.

Appointments

D. A. L. Saunders to the Chair of Architecture at the University of Adelaide, South Australia.

D. J. Cove to Professor of Genetics and Head of Department at Leeds University from 1 January 1978.

Dr R. S. Barnes, to Principal of Queen Elizabeth College from 1 April 1978.

Sir Richard Doll, OBE, Regius Professor of Medicine at the University of Oxford to chairman of the Committee of Management of the Institute of Cancer Research from 1 January 1978.

Professor F. L. Mastaglia, to the Chair of Experimental Neurology, University of Newcastle-upon-Tyne.

Dr M. J. Sewell, to a Personal Professorship in Mathematics at Reading University from 1 June 1977.

Dr R. F. Curtis, to Director of Agricultural Research Council Food Research Institute at Norwich on 1 October 1977.

D. Eccleston, to the Chair of Psychological Medicine from 1 October 1977, and also to Head of the Department of Psychological Medicine for five years from 1 October 1977.

Person to Person

Furnished 3/4-bedroom house, Manchester area, available 1 March 1978 to 28 February 1979. Contact M. Sampanthar, 25 Vaudrey Drive, Cheadle Hulme, Cheshire, UK.

Exchange furnished 5-bedroom house in Gainesville, Florida for similar convenient to Mill Hill, London, for 1 year, September 1977 to August 1978. Rental of London house also considered. Contact D. Duckworth, Box J-266, JHM Health Center, Gainesville, Florida 32610.

Exchange furnished, 7-room house south-east London, end August 1977 to July 1978, for house or apartment in Boston/Cambridge, Massachusetts area. Contact J. A. Patterson, Apt. C511, 77 Pond Avenue, Brookline, Massachusetts 02146.

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

International Commission for protection against enviromental mutagens and carcinogens

This commission (ICPEMC) has been established to primarily approach the problems involved in minimising hazards of the increasing variety of mutagenic chemicals to which human populations are exposed. Current knowledge is to be reviewed with the aim of formulating recommendations to serve as bases for regulatory action.

Lady Tata Memorial Trust

The Trustees of the Lady Tata Memorial Trust for research in leukaemia have made the following International Awards for the Academic Year 1977–78. R. de N. Bastos (Spain), L. Gauci (Great Britain), P. Mignatti (Italy) (2nd year awards); H. Jacobs (Great Britain), ¼. Ravid (Israel) (New awards); E. Cardoso (Portugal), G. Grosslerner (France) (New awards from April 1977).

Meetings

25–29 July, **International Conference on Solar Building Technology,** London, UK (The Secretariat, International Solar Building Conference, North East London Polytechnic, Forest Road, London, UK).

15–17 August, **Symposium on Prospecting in Areas of Glaciated Terrain,** Helsinki (The Institution of Mining and Metallurgy, 44 Portland Place, London, UK).

2–5 August, **Cryogenic Engineering/Materials Conference,** Boulder, Colorado (Bureau of Conferences and Institutes, Academy 217, 970 Aurora Avenue, University of Colorado at Boulder, Boulder, Colorado 80302, USA).

23–26 August, **5th International Conference on Chemical Thermodynamics,** Ronneby, Sweden (Fifth International Conference on Chemical Thermodynamics, c/o RESO Congress Service, S-105 24 Stockholm, Sweden).

24 August, **19th Canadian High Polymer Forum,** Ottawa (Secretary–Treasurer, 19th Canadian High Polymer Forum, National Research Council of Canada, Division of Chemistry, Montreal Road, Ottawa, Ontario, K1A 0R9, Canada).

28–30 August, **Satellite Symposium to the VI International Meeting of the International Society for Neurochemistry: Endorphins,** Brescia, Italy (F. G. Lorenzini, Via Monte Napoleone, 23, 20121 Milan, Italy).

31 August–2 September, **2nd Drag Reduction Conference,** Cambridge, UK (Organising Secretary, 2nd Drag Reduction Conference, BHRA Fluid Engineering, Cranfield, Bedford, UK).

12–16 September, **Symposium on Unconventional Photographic Systems,** Oxford, UK (Royal Photographic Society of Great Britain, 14 South Audley Street, London W1, UK).

14–16 September, **The Oil Industry and Microbial Ecosystems,** Warwick (The Institute of Petroleum, 61 New Cavendish Street, London W1, UK).

Peking exacts too high a price

THE cathedral city of Durham in the north of England is to be the site of an unusual battle in a week's time. For the question of the representation of the People's Republic of China in an international scientific union is to be put to the test, and, as in the international political bodies, the precondition of membership is to be the expulsion of Taiwan. There is by no means universal agreement that this is a worthy action.

Last year the International Union of the Geological Sciences (IUGS), meeting in Sydney, Australia, voted that the Academia Sinica of Taipei was not a valid body to be affiliated to IUGS, and went on to accept the Academia Sinica of Peking's application for membership. The Australian government had made its own small contribution to this decision by refusing visas to the Taiwanese delegates. The International Council of Scientific Unions (ICSU) didn't think much of all this and told IUGS to look into ways in which Taiwan could be reinstated.

The next union in line for a conditional application by the People's Republic of China was the International Union of Geodesy and Geophysics (IUGG), and its secretary-general, Professor P. Melchior of Brussels, is convening a council meeting, followed by an extraordinary general assembly (for the purposes of ratification) to coincide with a routine scientific gathering in Durham. Professor Melchior, who knows the People's Republic of China well, has a statement by the IUGG Bureau to fortify him. It is generally expected that this statement will assert that Taiwan is a province of the People's Republic, and so only Peking should represent China, and Taiwan's representation should cease.

Very few delegates would question the need for the People's Republic to be absorbed into international bodies, but it is to be hoped that many will baulk at the price. Gone, clearly, are the days when Taiwan could claim to represent mainland China, but equally, the day is still far off when Peking can claim *de facto* to be able to represent Taiwan, which indisputably runs and finances its own independent scientific activities. If Rhodesia can be a full member of IUGG alongside the United Kingdom, has the People's Republic, not yet even a member, strong grounds to dictate that the academy of an irritant government, running a quite respectable programme in geophysics, should be wiped off the international scene? Certainly such actions don't seem to match up in any way to the grand talk of the universality of science and its freedom from politics.

Many countries have already filed postal votes without bothering to hear the debate in Durham. Others are coming with instructions to admit the People's Republic, probably for the reason that they would rather be friendly with Peking than Taipei. So it is generally expected that Peking will have its way. Against all this the United Kingdom is to raise the question of universality and various constitutional issues —the latter a little unwillingly, because IUGG's constitution was not fashioned with such squabbles in mind and so could simply give legalistic nit-pickers a field day. The United States is expected to follow the same tack and will warn that back home the government won't like this sell-out of Taiwan by scientists and will look rather carefully and with due deliberation at the annual subscription that IUGG levies.

If the vote goes Peking's way, ICSU must, in logic, take at least as firm a line as it did with the geologists—firmer, preferably, because IUGG cannot claim to be ignorant of ICSU's views. And IUGG will have to face up to a problem in 1979 when it plans to hold a large meeting in Melbourne, Australia. ICSU rules now state that if any host country refuses visas to *bona fide* scientists wishing to attend a meeting, the relevant union must put pressure on that country. The pressure would presumably be in the form of a threat to move the meeting elsewhere or even cancel it. On the past form, Australia will turn away scientists from Taiwan. (IUGG may expel Taiwan, but it still recognises the right of qualified scientists from 'every part of the world' to participate as individuals in its meetings.) So IUGG must soon make its mind up not just over Taiwan's membership but also on some longer term consequences.

"If the international unions didn't exist, they wouldn't need to be invented", said one scientist last week who has had substantial experience with them. Even though they clearly serve a valuable purpose in helping a few scientists to travel and participate in international endeavours, the politicking that the People's Republic of China is trying to import could well seriously diminish what value the unions do possess. ☐

Cancer prevention: a question of priorities

Ernst L. Wynder of the American Health Foundation argues for the virtues of preventive medicine in combating cancer

RECENTLY, two independent studies have considered the relative contribution of environmental factors to the incidence of cancer*. Their common conclusion was that cancer is not an inevitable consequence of living, and that most cancers appear to be related to life-style factors. Estimates on the contribution of lifestyle to cancer incidence generally parallel each other (see below). The unanswered question is how we should react to our failure to curb those environmental factors that cause the continued high risk for many cancers.

As long ago as 1950, epidemiologic evidence established the causative association between cigarette smoking and lung cancer. Twenty-seven years later, tobacco usage still accounts for more than one-third of all male cancer deaths in the United States, in Britain and in other countries. Little did we expect that man's illusion of immortality would foster public apathy toward health messages related to smoking; nor did we foresee the unwillingness and inability of the medical establishment to assist significantly the motivation of the public to modify health behaviour. The opposition of commercial and agricultural interest, of course, was to be expected.

With the impact of these countervailing forces now so recognisable, the measure of success of a prevention-oriented approach to health maintenance seems to be inversely proportional to the responsibility one must assume for one's behaviour. It is thus far easier to launch a campaign directed against occupational and iatrogenic cancers than it is to infringe upon personal behaviour since, with the former, one can marshal the energy of government, the media and unions. It is no wonder that Doll regards the efforts necessary to solve the problem of nutrition-related cancers as an even more difficult task.

The identification and subsequent reduction of environmentally induced cancers requires a multidisciplinary undertaking, ranging from molecular biology to public health. Just as Comprehensive Clinical Cancer Centres can more effectively prescribe treatment regimens for cancer patients, a multi-faceted approach to environmental cancers would provide a vehicle for researchers to work in tandem on issues related to environmental cancers. The creation of Interdisciplinary Centres for Cancer Prevention is now called for.

The cross-fertilisation between epidemiologists, biologists, chemists and public health professionals has already proved constructive in focusing, directing and applying research efforts. For these efforts to succeed, however, the broad support of our academic and government institutions, and especially of the scientific community, is required.

Endeavours in the field of prevention are currently receiving only a fraction of available government or private funding, with the possible exception of investigations on industrial carcinogens. Economic considerations may force a change. As disease care costs continue to rise, prevention will necessarily attract greater attention to avoid bankrupting the existing medical care delivery system.

It has been said that those who do not learn from history are condemned to relive it. The lessons to be learned from scurvy, smallpox and cholera can be repeated for most cancers, as well as for other chronic conditions. Eradication of a disease is not dependent upon fully comprehending the disease mechanism. This applies to cancer prevention as well.

The question remains whether we will accept these lessons from history, particularly when personal and societal 'sacrifices' are demanded. A patient dying from a self-inflicted cancer would, in retrospect, certainly answer with an unqualified "yes." But what of the rest of us looking toward the future? The development and support of Interdisciplinary Centres for Cancer Prevention could help us reach the proper perspective on the values of preventive medicine. It could also draw us closer to the day when what we know to be avoidable disease will no longer plague the health and economic fibres of ours and future generations. □

Soviet genetics: new controversy

Zhores Medvedev reviews the development of human genetics in the Soviet Union since Lysenko

T. D. LYSENKO dominated Soviet genetics and biology for more than 25 years. In 1965, when his domination was over, genuine science was quickly restored to research and education. It was generally assumed that his political and ideological interference in the nature of genetic problems had been completely wrong and harmful. The notions of a 'Soviet' and a 'bourgeois' natural science had been almost forgotten. In spite of Lysenko's long 'dictatorship', there were still quite a few prominent, enthusiastic geneticists of the older generation who could build up research again, write new textbooks for schools and universities, and support and teach the younger generation.

For human genetics, however, the position was much more bleak. The subject was declared racialist and was completely destroyed in 1936–38. Most of its prominent representatives were arrested, and not one of them was found alive when Khruschev dismantled the GULAG camp-prison system in 1956. The liquidation of Soviet human geneticists during the pre-war period explains why medical and particularly human genetics lagged behind in the rapid development of genetics after 1965.

The problems of human genetics were discussed only very briefly. In the first Soviet textbook on general genetics, written by Professor M. E. Lobashov and published in 1967, attention focused on the pattern of human chromosomes and immunogenetics. In only one chapter did Lobashov really repeat the old 'clichés' on the bourgeosie's misuse of human genetics. Through human genetics, he claimed, this had tried to "justify the exploitation of one class by another, antagonism between different nations and creation of the racialist theories". Lobashov also made some very positive statements about eugenics and considered that previous errors in this branch of human genetics did not necessarily indicate that it could not be developed into a useful field of research. Lobashov's view was that individuals in a human population, although equal in the social sense, have different genotypes and far from identical intellectual possibilities. These inherited differences had to be taken into consideration by educational training programmes so that the individual's potential could be released and developed.

At the same time, I. T. Frolov, philosopher and senior official of the Department of Science of the Central Committee of the Communist Party of the USSR, published a small booklet entitled *Methodological Problems of Genetics*. His main points were designed to prove that the collapse of Lysenko's pseudoscience would not in any way diminish the importance and validity of Marxist dialectic-materialist philosophy for biology and natural sciences in general. Lysenko simply did not use this philosophy correctly; he falsified and distorted both biology and dialectical materialism.

With his philosophical criticism of Lysenko's ideas, Frolov attempted to present the Marxist background to modern classical genetics, biochemical genetics and evolution. Human genetics were not mentioned in his essay at all, as if they were not part of the problem; the rehabilitation of genetics stopped short, neither ideologists nor scientists being able to analyse human genetics. Nobody wanted just to acquire knowledge from abroad, but all the roots of Soviet human genetics had been completely destroyed, and as yet nothing could appear from the rubble.

Development inevitable

The logic of science and the practical needs of medicine, however, made the development of human and medical genetics in the USSR inevitable. The Academy of Medical Sciences started to consider establishing a research institute in the field, and the leading figures of genetics and biology, none of whom had real practical knowledge of human or medical genetics, started discussing their possible task.

Initially, the discussions were very peaceful and pragmatic with nobody, quite understandably, wanting to take the lead. Among those taking part, Academician Nikolai Dubinin, Director of the newly-established Institute of General Genetics, was considered to be the main authority. His expertise lay in the field of *Drosophila* genetics. The next most prominent but most popular of the geneticists was Academician Boris Astraurov. He was elected the first President of the Society of Geneticists of the Soviet Union, which was established in 1966, and an expert on silk worm genetics. He established the Institute of Developmental Biology which excluded research on human genetics.

Of the others actively involved in the discussions, Professor Dmitry Beliaev, Director of Novosibirsk Institute of Cytology and Genetics, had experimented in the genetics of rabbits and some rodents. The man most excited about human genetics, Dr Vladimir Effroimson, was a silk worm geneticist whose very wide knowledge of medical genetics (he published the first Soviet book on medical genetics in 1963) was purely theoretical. The other members of the discussions came from similar backgrounds: Professor S. J. Alikhanian was Director of the Institute of Bacterial Genetics and Selection; A. A. Prokofieva-Belgovskaja and N. P. Bochkov were cytologists; N. P. Timofeev-Resovsky and R. L. Berg, drosophilists.

Although the project to establish the research institute on human genetics was generally supported, its organisation and priorities were not established in the meetings and discussions sponsored either by the Medical Academy or by the newly-created All-Union Society of Geneticists. The peaceful but not yet very productive discussions, however, were suddenly sharpened by Dubinin, who, like Frolov one year earlier, published a small popular book under the almost identical title, *Some Methodological Problems of Genetics*. The essay strongly politicised the discussion and opened up a new division among geneticists who only recently had represented a strong and friendly joint front against Lysenko.

Dubinin, introduced by the publisher as "a famous geneticist who had great influence on the development of Soviet and world genetics", started his essay in the usual demagogic style of his former Lysenkoist opponents. The methodological principles of the modern natural sciences, he claimed, had been founded by Lenin in his work *Materialism and Empirio-criticism* (1909). This had eternal importance for the further development of philosophy and all natural sciences, genetics in particular. After a short description of the history of modern genetics, with more than generous attention to Dubinin's own contributions and frequent quotations from Marx, Engels and Lenin, Dubinin unexpectedly made a statement on human genetics, differing little from Lysenko's approach to the field.

> "In research on human genetics the main task is to realise that the human race during its development excluded itself from the evolution of other animals . . . Now social factors only—class struggle, industrial, cultural and scientific progress—determine human evolution. Anthropogenesis is completed and ended by the appearance of consciousness. Now social factors are primary and biological factors secondary". (p. 60).

At first this statement did not look

Zhores Medvedev is at the Division of Genetics, National Institute of Medical Research, London.

out of place. Nobody considered Dubinin an expert on human genetics and his colleagues and friends tried to explain to him that genetic laws and principles apply equally to all animals and that man is no exception. Very quickly, however, it became clear that the statement quoted above was not accidental; it was part of a developed system of views which recognised the human race as a qualitatively different, new and final stage of animal evolution.

Two years later, in 1970, Dubinin published another book for the general reader called *Genetics and Human Future*. By this time his ideas about the qualitative biological gap between man and other animals had developed. He tried to show that genetic make-up in humans bears no relation to the formation of personality. According to Dubinin's theory, human development from birth is determined by "social inheritance", everybody having potentially equal intellectual capabilities. Social inheritance is determined by the character of society itself and so far only the Communist societies can create the favourable conditions for the full development of human potential.

This book provoked more open discussion. Both sides tried to keep it outside serious academic journals, mostly because the discussion was based on opinions, not on facts or research. But both Astaurov and Effroimson wrote critical essays which were published in the popular literary magazine *Novy Mir* in 1971. Frolov, then Editor-in-Chief of the journal *Voprosy Filosofii* (Problems of Philosophy), organised a round-table discussion on human genetics, also sponsored by the Advisory Research Council, on the Problems of Philosophy of Nature at the Presidium of the Academy of Sciences of the USSR. It was clear from the discussion which was published in *Voprosy Filosofii* in 1972, that Dubinin's view received very little support.

Narrow objectives

The new Institute of Medical Genetics, which was finally established in 1971 within the Academy of Medical Sciences of the USSR, did not have the organisation to make the study of all aspects of human genetics possible. It was given narrow objectives and a comparatively young director, Nikolai Bochkov, a medical cytologist. Bochkov's appointment was supported by Dubinin who expected him to be an ally in the personal confrontations which now made up the discussion.

In 1973 Dubinin published *Vechnoe Dyizhenie* (Perpetual Motion), a rather self-promoting autobiography. Reviewed very widely and favourably in the official press, it distorted the factual history of Soviet genetics and gave a very mild version of the Lysenko controversy. In it, though, Dubinin tried to reply to his critics and to formulate the main principles of his vision of human genetics.

> ". . . The attempts to whitewash eugenics and to use for this purpose new genetic discoveries had been made by B. L. Astaurov, A. A. Neifakh and M. D. Golubovsky. V. P. Effroimson developed wrong views about genetic determination of intellectual and personal characteristics of man. This trend started to be an ideological danger. Again alien ideology tried to poison the clear sources of our science. I tried to make an uncompromised denunciation of this ideologically harmful attitude. Alas, I met a small, but well united group of opponents; B. L. Astaurov, S. M. Gershenson, S. I. Alikanian, D. K. Beliaev who defended their wrong position. This worried me and proved that some old geneticists do not understand Marxist ideas about human race and principles of society which is the only factor determining the intellectual specificity of man . . ." (p. 434).

‘According to Dubinin, human development is determined by "social inheritance", which is determined by the character of society itself. Only the Communist societies can create the favourable conditions for the full development of human potential’

Dubinin also tried to develop the distinction between the genetic control of physiological and psychological characteristics of human individuals. Genes, according to his view, determine the programme of development, lifespan, some pathologies, expectancy of heart troubles, cancer and resistance to infections. The shape of nose and mouth, or height, are also inherited traits. However, personality and intellect, he claimed, depend not on genes but only on social environment and self-training; their possibilities are unlimited. As soon as man is able to think consciously, he isolates himself from the laws of biology. All "normal" persons are psychologically and mentally equal at birth and so there is no reason for taking the racialist approach when talking about the quality of human genotypes with regard to intellect.

> ". . . Let us remember the story of emigration from Russia of many representatives of bourgeois art, scientific and thechnological elite after the October Revolution. Some eugenicists considered this exodus as an irretrievable loss of valuable genes. But this was nonsense. New talents from grass roots through Revolution found their way to lead the country, the Party, to create new science, new art, to create the great Soviet Union! . . . This fact illustrates that the creation of personality does not depend on genes, but is induced by the information of social environment." (p. 426).
